On the 19th the patient was put on milk diet, given saline cathartics, etc., and on the 21st the operation was performed. Every preparation had been made with the most sedulous care, and every precaution taken to avoid all possible sources of sepsis. The patient was in the best condition possible for her to be. Dr. Frey administered the ether, Dr. H. C. Coe and Dr. C. N. D. Jones assisted in the operation. I made an incision of four and a half inches in the abdominal walls, found the uterus wedged into the pelvis and bound in posteriorly by firm adhesions. Both ovaries were very much enlarged, evidently with some abscess formation, and both, with their corresponding tubes, were removed. Though handled with the greatest care, the right one ruptured, discharging a considerable amount of pus, which was caught on sponges. The adhesions about the tumor were separated and the tumor thus rendered movable. It had been before decided to do entire hysterectomy, and this procedure still seemed to be the most feasible; so, after freeing the tumor, the abdominal wound temporarily closed, I commenced at once to separate the vaginal attachments. Here enormous difficulties were encountered, colpo-hysterectomy was as nothing to it; the elongated cervix was adherent throughout its whole extent by firm fibrous attachments. While I was separating these attachments and freeing the cervix, Dr. C. N. D. Jones and Dr. H. C. Coe greatly assisted me. The broad ligaments were clamped from below, the entire mass was removed through the abdominal wound, and the abdomen was temporarily packed with gauze. The operation was completed in about forty minutes At 2.30 P.M., pulse 114. At 5.30 P.M. the patient asked for milk, said she was hungry. At 6 P.M., temperature 99½° F. At 9 P.M., pulse 119. During the afternoon and evening she slept at intervals, and occasionally took brandy-and-water. She had no nausea.

The indications now were that the patient would make a good recovery; she took nourishment during the day, and slept quietly; but in the evening there began to be indications of shock and profound septicæmia. On Wednesday, the third day, there was scarce a teaspoonful of discharge in the drainage-tube, and this had the appearance of dirty, offensive pus. I sent a portion of this to Dr. C. Heitzman for microscopical examination. He replied that "there was an old peritoneal abscess, some of the pus-corpuscles were already in a state of fatty degeneration." This abscess was probably on the right side near the liver, and its existence would explain many of the patient's previous symptoms. It probably ruptured on the second day, discharging its contents into the peritoneal cavity, and thus fully saturating the system with its poison, which circumstance at once destroyed all possible chance of the patient's recovery. She continued to grow worse till 9 P.M., Thursday. After death the discharges from rectum and vagina were extremely offensive. No autopsy was made.

This patient should have been operated on years before. The whole difficulty in this case, and the cause of finally fatal results, was in this delay, and delay will be found the main cause of the difficulty in every serious or fatal case. As Joseph Price says: "The safety is in early operating." Lawson Tait wrote me in 1886: "The whole gist of modern abdominal surgery lies in earnest and continuous plea for early interference," and he says in his last work on diseases of women and abdominal surgery: "The whole of my experience in every department of abdominal surgery is one continuous outcry against delay."

Microscopical Examination of the Ovaries.—The left ovary was the seat of the most remarkable change, suppurating endothelioma. Portions of the ovary not occupied by the endothelioma were in a state of intense acute or subacute oöphoritis. There were anomalous menstrual bodies which were also in a state of intense inflammation, changing into endothelioma. The ova were diseased, many of them broken up into medullary corpuscles.

By this suppuration of the endothelioma I was enabled to study all the tissue changes leading to the formation of pus from a previous endothelial tissue. It is a pathological process in an already pathological tissue.

The tissue changes are as follows: The endothelia in portions not yet affected by the inflammation are coarsely granular, and many of the granules exhibit a yellowish lustre characteristic of hæmatoblasts. Between the endothelia, or groups thereof, are blood-vessels holding red blood-corpuscles. The first change noticeable in the endothelia is their becoming more coarsely granular, and a conspicuous augmentation of the hæmatoblasts. Through coalescence of the granules yellow and highly refracting lumps are discernible. Next, the large lumps of the previous endothelia split up into a number of smaller ones, which still remain interconnected by means of delicate offshoots of lining matter. From these lumps, greatly varying in size, medullary or inflammatory corpuscles originate, and these, by progressing from the solid or vac-

uoled condition of lining matter into the reticulated state of protoplasm, become nucleated protoplasmic bodies. After a tearing asunder of their bodies isolated protoplasmic bodies arise, which are now true pus corpuscles. Another mode of change from endothelia into pus-

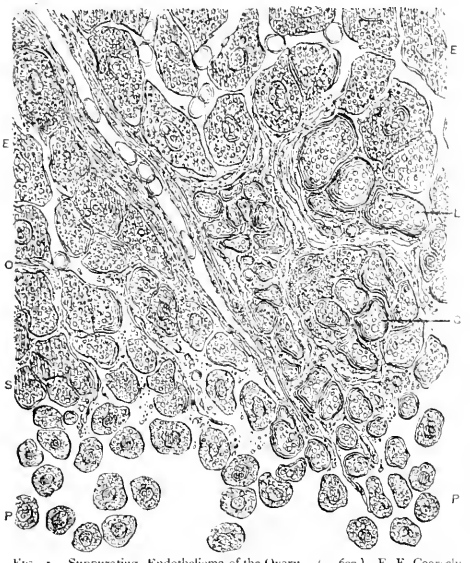

FIG. 1.—Suppurating Endothelioma of the Ovary. (× 600.) E, E, Coarsely granular endothelia; C, blood-vessel, with marked adventitial coat; O, obliterated vessel between endothelia; L, vacuoled lumps from previous endothelia; G, groups of medullary corpuscles sprung from endothelia; S, endothelia split up into medullary corpuscles; P, P, pus-corpuscles.

corpuscles is this: Two or several endothelia coalesce by a liquefaction of the intervening cement substance into granular lumps of protoplasm, which directly split up, first into inflammatory, and then into pus-corpuscles. The blood-vessels between the endothelia, soon after the inflammatory changes have started, become transformed into solid tracts of fibrous connective tissue, which likewise shares in the production of inflammatory, and afterward pus-corpuscles.

Cohnheim claims that in the process of suppuration all the inflammatory and pus-corpuscles are nothing but emigrated colorless blood-corpuscles, the tissue elements themselves taking no part whatever in the production of such corpuscles. In these specimens I could see, step by step, the transformation of the elements of endothelioma into pus-corpuscles. This proved the fallacy of Cohnheim's theory and strongly supports the assertions of S. Stricker and C. Heitzman to the effect that the constituent elements of living tissues themselves become transformed first into inflammatory and at last into pus-corpuscles.

Thus I consider pus a disintegrated tissue, whether this tissue is normal or pathological.

The right ovary, which had ruptured, was the seat of a large abscess. The tissue bordering this abscess and for some distance was in a state of intense acute oöphoritis. The stroma of the whole ovary showed long-existing disease and consequent structural changes.

In the midst of the acute and subacute oöphoritis there were anomalous menstrual bodies, also in a state of intense acute and subacute inflammation, while some were waxy or changing into endothelioma. There were some small cysts with intensely inflamed walls. The walls of many of the blood-vessels were waxy, some breaking down into inflammatory corpuscles. The endothelia of the arteries were coarsely granular, and had become detached, as is usually seen in arteries situated in inflamed tissue. Many of the arteries were in a choked condition. The lymph vessels were waxy. The ova of this ovary also showed a diseased condition, some undergoing a retrograde progress, the yolk and maculæ germativa were broken up into medullary corpuscles, and much of the ovarian stroma around them was in waxy degeneration.

There was interstitial salpingitis of the tubes, some muscles of the walls were completely destroyed by the inflammatory action. Also the mucosa of the tubes was intensely inflamed, and there was peripheral salpingitis.

The tumor of the uterus, after removal, weighed six pounds, and had a longitudinal diameter of five and one-half inches. The cervical portion attached to it was about three inches in length, but not enlarged. A transverse section through the tumor exhibited a central portion, two and one-half inches in length and one and one half in breadth, composed of a soft, somewhat cauliflower like mass, in the immediate vicinity of which the firm and dense tissue of the tumor commenced. The latter showed a distinct cortical layer, conspicuous by a concentric stratification.

Anteriorly, in the lowest portion of the cortex, there was imbedded a nodule of an irregular striated structure, the size of an English walnut. The rest of the tumor exhibited irregular striations and stratifications. About an inch above the lower circumference of the tumor a curved slit-like cavity could be seen, parallel with the lower contour of the tumor, about two inches in length. This was the remnant of the uterine cavity. A probe introduced into the cervical canal would pass without difficulty into this slit. The enormously elongated cervical portion showed a transverse laceration of the cervix, and a noticeably elongated posterior lip.

Sections through any portion of this tumor proved, under the microscope, to be a myofibroma, composed mainly of smooth muscle-fibres, arranged in bundles, which interlace in all directions without regularity. The muscle-fibres are of an unusually large size and distinctly supplied with rod-like and granular nuclei. The latter were especially well defined in the transverse sections of the mus-

cle-fibres. Between the single fibres, as well as groups of such fibres, a considerable amount of fibrous connective tissue was present, but less than of the smooth muscle-tissue. In longitudinal sections of the muscle-bundles it was impossible, as is usual in such tumors, to tell the

difference between muscle and connective tissue, whereas in transverse sections the difference could be easily seen.

One of the most notable features of this myofibroma was that in the lower and middle portions its tissue was freely mixed with myxomatous and myxofibrous tissue. The fields of this tissue greatly varied in size in different

FIG. 3.—Myofibroma of the Uterus with Interspersed Myxomatous Fields. F, F, Myofibroma; M, M, myxoma and myxofibroma.

portions of the tumor. The largest fields were seen in that portion of the tumor near the uterine cavity.

The myxofibrous tissue as a rule abruptly bordered the myxomatous fields, although the connective tissue trabeculæ of the latter could everywhere be seen in connection with the fibrous connective tissue of the myxomatous portion. The trabeculæ in the myxomatous fields were made up either of single fibres or bundles of such fibres interlacing without regularity. The meshes produced by the reticular arrangement of the trabeculæ were filled with a light myxomatous basis-substance. Evidently the myxomatous tissue was a secondary formation in the myxofibroma, therefore a metaplasia of muscle and fibrous connective tissue into a myxomatous and myxofibrous connective tissue. Such a transition of different though kindred tissue varieties was possible only by an intervening formation of medullary or embryonal tissue. Thus we see in the already formed myxomatous fields clusters of medullary or embryonal corpuscles, sprung both from the muscle-fibres and the intervening connective tissue, with a simultaneous dissolution or liquefaction of the basis-substance of the latter. The image of such medullary portions closely resembles that of inflammation, which we also know to be a reduction of an already formed tissue to its embryonal or medullary condition. The myxofibrous tissue of the tumor was not only found inflamed but in some places the changed myxomatous portion was becoming waxy.

The most central portions of the tumor, which was, as stated above, soft, almost jelly like, and of a structure somewhat resembling cauliflower, under the microscope exhibited peculiar tissue changes.

In the neighborhood of the soft portions the bundles of smooth muscle-fibres appeared pushed apart by fields of an embryonal or medullary tissue, which sprung both from the connective and smooth muscle-tissue of the tumor. Near the softened parts the tissue was found disintegrated into a granular mass, in which no structure, but only small tracts of fibrous connective tissue, with interspersed granules and glistening irregular lumps, were seen. No doubt the disintegration of the tissue was due to a serious inundation and subsequent hydropic swelling of the medullary tissue, the elements of which were in a condition termed coagulation necrosis by Weigert, or necrobiosis by Virchow. Owing to disturbances in the nutrition of the central portions of the tumor, first a reduction and afterward a disintegration has taken place, rather unusual in tumors of such a pronounced degree of consistency as that of myofibroma. Some of the muscle-fibres of the myofibroma escape the reduction into medullary tissue and remain directly traceable into the softened and disintegrated portion. Such fibres become simply hydropic, as best exhibited by their transverse sections, which in this situation have assumed almost the size and shape of epithelia. Other fibres directly enter the condition of coagulation necrosis, proven by the lack of carmine stain of such fibres. The living portions of the myofibroma readily stain with a solution of ammoniacal carmine, whereas the necrotic portions remain entirely untouched by the carmine, and by their yellowish tint become conspicuous.

In looking at this tumor, its position, and the circumstances of the case, what would suggest itself as the most desirable method for its removal—one that would take the shortest time, give the least shock to the patient, and contribute most to her welfare and safe recovery?

In 1886 I saw Austria's great surgeon, Billroth, in his management of the pedicle intraperitoneally; but in this case would not such manipulations have been extremely trying or impossible? The same year I saw the unrivalled surgeon, Lawson Tait, of Birmingham, and Dr. Bantock, of London, treat the pedicle extraperitoneally in suprapubic hysterectomy; but even for this pro-

cedure would there not have been almost insuperable difficulties?

At the meeting of the New York Obstetrical Society, June 15, 1889, three eminent surgeons of this country gave their preferred methods, and each thereby had ob-

tained most excellent results. Dr. C. C. Lee gave preference to the clamp—out of eleven operations he had ten recoveries;[1] but would the clamp have been elected for this case? Dr. Wylie's excellent method as he describes it: "First ties the broad ligaments with silk, then puts on the wire, inclosing only the stump; thus he has three stumps brought together in a way to prevent the entrance of pus into the tissue of the broad ligament." Dr. Polk first ligates the broad ligaments, enucleates the uterus as low down as it is proposed to make the amputation, and places the serre-nœud between the peritoneal covering and uterine tissue proper, and then stitches the sac, the bottom of which is represented by the stump of the uterus, to the abdominal walls. This is a beautiful plan to avoid as much as possible the danger and evils of the stump. But would any of these procedures meet the indications of this case?

Surgeons have long recognized the dangers of the stump, whether much or little is left, or whether treated intra- or extra-peritoneally. Professor William Polk at the same meeting said: "It occurs to me that leaving a large suppurating, or rather gangrenous, stump is a surgical fault seriously threatening the life of the patient, and that improved means should be devised whereby it can be got rid of. I should like to take the views of the members upon the propriety of total extirpation of the uterus. I believe it is time to look about for means of getting rid of the slowly sloughing stump, which is constantly a source of danger in addition to what pertains to ordinary laparotomies."

May 15, 1887, I performed supra-pubic hysterectomy for a myoma weighing, as then estimated, nine pounds. The stump was treated extraperitoneally; patient was able to sit up the thirty-fifth day, left the hospital in two months in good condition, and since has reported herself in excellent health. When I presented the tumor before the New York Pathological Society, November 23, 1887, I stated that I believed a better and more natural procedure would have been, after opening the abdominal walls—being assured of the condition of affairs, and liberating any adhesions that might exist—then to have severed the vaginal connections, as in colpo-hysterectomy, and so remove the entire uterus. Or, if the body of the tumor or uterus were removed through abdominal incision, then to remove the uterine stump per vaginam, and, after "la toilette du peritoine," close the abdominal walls and leave the vaginal opening as the best and most natural mode of effecting drainage. I also gave the following reasons for favoring this procedure: 1, It would shorten the operation; 2, would be less shock to the patient; 3, would lessen the dangers of the operation; 4, the patient would make a rapid recovery.

I carried this method out February 16, 1888, for a tumor weighing thirteen and a half pounds.[2] The patient came to my office January 17, 1888. Forty years of age, twice married, and no children. A uterine myoma extended from the cervix to within an inch of the ensiform cartilage, and was larger than the uterus at term. It interfered with her breathing and gave rise to distressing neuralgic pains; her emaciated body was only a framework to support the growth. When told by a physician whom she consulted that the attempt to remove the tumor would cause death, she said that she would rather die than live, that she had often studied how she might destroy herself.

This patient entered the Woman's Hospital of Brooklyn February 5, 1888, operation eleven days after. The incisions in the abdominal walls extended two inches above the umbilicus. The tumor was lifted out by Tait's screw; a temporary rope clamp[3] was then thrown around the tumor and a great portion removed; Koeberle's clamp was screwed on lower down, when other portions were enucleated. The pedicle thus secured consisted of a mass of tumors, one of which was three inches in diameter, all closely packed in the lower pelvis. I proceeded at once to remove this portion as in vaginal hysterectomy. Dr. Charles Jones took charge of the abdominal wound, temporarily closed and covered with aseptic gauze, and greatly assisted me by pushing down the cervix with the contained tumor.

After separating the vaginal connections, large forceps were passed up from below, guided by the hand of my assistant, to clamp each of the broad ligaments. The size of the tumor in the cervix and around rendered it necessary to deliver the mass through the abdominal opening. The peritoneal cavity was washed out, the vaginal wound left open for drainage and treated as in vaginal hysterectomy. The large forceps which clamped the broad ligaments projected from the vaginal opening and were left on for thirty-six hours. Smaller forceps clamping the vaginal wound were left on twelve or twenty hours. The patient made a most rapid recovery, was up on the seventh day, able to sit up on the eleventh, and was practically well on the twelfth or fourteenth day. No such results could possibly have been secured if the stump had been left.[1]

By thus removing the cervix, or entire uterus, we not only got clear of the stump, but of the great mass of loose tissue which surrounded it and which, if it had remained, would doubtless have produced the most serious consequences.[2]

Goffe's method, as reported by the *New York Obstetrical Journal*, is, as he describes it, "taking out the whole of the uterus except a bit of the cervix, covering this over with peritoneum." But in all his cases, as he reports them, the temperature went up the fourth or fifth day, which, says Dr. Goffe, "means suppuration under the flap, with danger of the pus bursting into the peritoneal cavity;" so in each case he dilated the cervix, drained, and irrigated. Of one he said, "a gentle amount of pressure caused the exit of about half an ounce of pus and broken-down tissue." The same procedures are used by Dr. A. P. Dudley. "He dissects out the uterus to about three-fourths of an inch of the cervix." The third day there is the same rise of temperature, the same process of dilating for discharge of pus. Thus, invariably, a certain amount of suppuration seems to accompany this method, so, with "a bit of the cervix left," there cannot be, as Dr. Goffe expresses it, "all the elements of safety." At a meeting of the New York Obstetrical Society, November 5, 1889, when Dr. Boldt presented "an interstitial uterine fibroid," removed by my method of total extirpation of the uterus. Dr. Dudley inquired what advantage there is in removing all the cervix over that form of hysterectomy which leaves part of the cervix as a stump. Dr. Boldt well replied, "By leaving a portion of the stump the patient is exposed somewhat to sepsis, which can be avoided by complete hysterectomy."

In the *Medical News* of July 7, 1889, Dr. Lewis A. Stimson reports a case of hysterectomy, removing the whole organ through the abdominal wound, commencing, as Dr. Stimson states, by "a preliminary ligaturing of the uterine arteries." He says: "The outer portion of each broad ligament was clamped with hæmostatic forceps. The uterus was peeled away from the peritoneum, well down to the cervix, and then its body cut away by this transverse cut. The stump of the uterus was seized with the volsella, the cervix rapidly dissected out until the

[1] In 1885 I witnessed Dr. Lee perform supra-pubic hysterectomy for an immense cystic fibroid. The patient did well. I was privileged to see her during convalescence.

[2] This case was reported in the New York Medical Journal, August 25, and September 1, 1888, and by Dr. C. N. D. Jones in the International Journal of Surgery and Antiseptics, April, 1888.

[3] Dr. C. N. D. Jones's modification of Tait's temporary clamp. See New York Medical Journal, June, 1888.

[1] In my report of the case in the New York Medical Journal, August 25, and September 1, 1888, an oversight was made in representing the large forceps as projecting from the abdominal wound. I know of no way to account for this error, except that at the time of that writing I performed a laparotomy for removing a cancerous ovary adherent to the pelvic walls, and the hemorrhages were so uncontrollable that it was necessary to clamp the fascia of the pelvic wall, and necessarily the forceps had to be of sufficient length to project through the abdominal wound.

[2] July 7, 1890, patient said she was in excellent health, every way comfortable.

vagina was opened into. After opening had been made the finger was withdrawn and reintroduced through the opening in the vagina to serve as a guide in the divisions of the remaining attachments of the cervix."

This is removing the stump with the tumor, and is practically the method I proposed; differs only in the manner of performing it, viz., the cervix instead of being separated as per vaginal hysterectomy, is "dissected out" from above. By thus separating the "attachments of the cervix" by dissecting it out from above there is more exposure of the abdominal cavity and, necessarily, more danger of wounding the bladder, the uterus, the rectum, etc. One great gain of removing the stump as per vaginal hysterectomy is that the peritoneal cavity need not be kept open so long, in many instances only a few minutes, the principal work being performed from below and through the vagina, making the whole operation not much more than a vaginal hysterectomy, and thus immensely simplifying this grave operation, which T. A. Emmett says "is the most difficult one a surgeon can be called upon to encounter." The prolonged opening of the peritoneal cavity which is necessary in the other methods seriously exposes some of the vital organs of the body to injury, exposes to some extent the great organic nerve-centres, thereby causing a greater shock to the patient, more completely exhausting her and fearfully increasing the liability of sepsis. Probably these factors will explain why Freund's method has been attended with such fatality. The separation of the stump through the vagina or from below is easier for the surgeon, infinitely more tolerable to the patient, and attended with greater safety and better results. Women seem wonderfully tolerant of it. It is almost like the parturient act, it is in the line of all the efforts and straining of the abdominal muscles; while in pulling up the pedicle the peculiar tension is opposed to all the efforts of nature and is a continued shock to the patient. So tolerant do women seem to be of vaginal hysterectomy, that in some instances the next day after the operation they appear as if nothing had happened, or as if they had simply passed through a normal parturition. On November 28, 1887, I removed the entire uterus from a woman who had not been able to sit up for months, completely exhausted by the constant watery and bloody discharges; she was carried in the nurse's arms to the operating table, so weak that we feared the breath would leave her body before the operation was finished. The operation lasted twenty-three minutes. The next day she appeared less exhausted than before the operation, gained strength rapidly, and on December 15th she was able to sit up, on the 23d left the hospital apparently well, and since has been able to assume the charge of her large family.

The plan of Dr. Stimson, of first tying the ovarian arteries, seems to me most excellent, and is an easy way of controlling hemorrhage; but Dr. Polk said at the meeting reported, May, 1890, that "it was unnecessary, for one could ligate *en masse* without any difficulty." He said, further, "ligating *en masse* shortens the operation." Dr. Bantock reported in the *British Gynecological Journal* for 1890, page 75, "the very first case in which he removed a fibroid tumor from the uterus he secured both the ovarian and uterine arteries separately and then put a serre-nœud around the body of the uterus, and it was extraordinary how much bleeding he got."

At the meeting of the New York Obstetrical Society, February 18, 1890, Dr. Polk incidentally remarked: "The operation introduced into this country by Dr. L. A. Stimson, of removing the entire uterus including the cervix." Is not this a mistake? Dr. Stimson says his first two cases were reported to the New York Surgical Society, January 9, 1889, published in the New York *Medical Journal* March 9, 1889. My first case was reported to the New York Pathological Society February 22, 1888, and published in the New York *Medical Journal* August 25, and September 1, 1888.

Dr. Krug said at the same meeting "he had yet to find a case recorded in which laparo-vaginal hysterectomy (opening the abdomen first and then finishing it per vaginam) had been done intentionally from the first. In most cases when the combined method had been adopted the operator had started to do vaginal hysterectomy."

The doctor will see from the published report that I not only "intended" it when I commenced the operation, but gave notice nearly three months beforehand that I would adopt the plan. Since, I have pursued the same method in two instances, with the previous intention, and the full conviction, that the procedure would give a more rapid recovery, than if the stump were left, however it might be treated. It did happen that in 1888 I commenced to do vaginal hysterectomy with no idea of opening the abdomen, but found the tubes and ovaries so adherent from secondary infiltration that it was necessary to make abdominal sections in order to proceed with the operation.

In the *Journal of Obstetrics*, 1889, is a report of the proceedings of the Chicago Gyneocological Society for December 16, 1888. At this meeting Dr. E. C. Dudley, in presenting a case of vaginal hysterectomy, is quoted as follows: "This operation may have a wider field than ordinary vaginal hysterectomy. I have determined that the next case I have of uterine myoma, when supra-vaginal hysterectomy would ordinarly be performed, to open the abdomen, lift the the tumor out through the abdominal wound, and then, instead of using the serre-nœud, to secure the broad ligament by means of lock forceps in vagina."

In this there is no intimation given of removing the cervix, the doctor merely calls attention to securing the broad ligaments with forceps instead of using the serre-nœud. In reply to the remark by Dr. Dudley, Dr. C. N. D. Jones wrote a letter, April 11, 1888, to the *American Journal of Obstetrics*, "On removal of Uterine Myoma by Combined Abdominal and Vaginal Hysterectomy," in which he said: "If Dr. Dudley will examine the MEDICAL RECORD for December 24, 1887, he will find that he is anticipated in this suggestion. In the proceedings of the New York Pathological Society, held November 23, 1887, and reported in this number of the RECORD, Dr. Mary A. Dixon Jones presented a modification of the operation, namely, liberating the vaginal walls and removing the uterus entirely. February 16, 1888, this conception was put into execution. The abdomen was first opened and the mass of the tumor removed above a wire serre-nœud, which encircled the cervix, the abdomen was then temporarily closed and the vaginal connections were severed from below. This was the most difficult part of the whole operation, from the fact that a portion of the myoma occupied the cervix. After the cervix was freed the thumb and index-finger of an assistant was made to straddle the right broad ligament from within the pelvis, so as to serve for a guide in passing the blades of a pair of large forceps from below around the broad ligament. The remaining uterine connections were rapidly secured with ligatures and forceps. The loss of blood was trifling."

In the meeting of the New York Obstetrical Society February 18, 1890, Dr. C. Cleveland read a paper entitled, "Laparo-vaginal Hysterectomy." He said: "I first made a short abdominal incision, the opening in the peritoneum I temporarily closed by a small clamp, and covered the wound with an aseptic pad. I then proceeded as in vaginal hysterectomy. The forceps were applied from below, my hand guiding them to the top of the broad ligament."

Dr. Krug's method as then reported was: "First an abdominal incision, the uterus lifted out, its attachments tied till Douglas's sac is reached, the operation completed as is usual in vaginal hysterectomy. No clamps were used, ligatures were applied, but with much difficulty."

Dr. Hanks reported at the same meeting of the New York Obstetrical Society: "He commenced with vaginal hysterectomy, afterward made an abdominal incision, and

with his finger in the abdomen directed the forceps introduced from below by his assistant, the uterus was then separated and removed through the abdominal incision."

These were all cases of cancer. I refer to them only as methods of clamping the broad ligament from below, a procedure that I think was first carried out in the case I reported on February 16, 1888.

Dr. Mendes De Leon, of Amsterdam, wrote me October 20, 1888: "Only yesterday I returned from a trip to Berlin. Martin told me he had performed four hysterectomies, with vaginal extirpation of the pedicle. As soon as he will reach the series of ten he intends to publish it. Is this method of tying the pedicle yours or his? I am very anxious to know more about this question. Perhaps you may find time to let me know one of these days."

Professor A. Martin, of Berlin, was in this country only two months before I presented the subject to the Pathological Society. In several of his addresses while here he spoke of the treatment of the pedicle, strongly favored the intraperitoneal method; so far as I know he did not mention the vaginal extirpation of the stump, nor did any one else previous to my publication in November, 1887.

Dr. T. J. Crofford, of Memphis, Tenn., sent a communication to the *American Journal of Obstetrics*, May, 1889, entitled, "A New Method of Performing Hysterectomy." He says: "I long for something simple;" and adds: "I propose complete removal of the womb as against all other methods of performing hysterectomy."

It delights me to know that Dr. Crofford so entirely approves of my procedure, though he made no reference in any way to me or my work. It is also pleasant to see the similarity in thought, as may be noticed in the following quotations from my paper, November 23, 1887, and from Dr. Crofford's article, May, 1889.

"In both methods of operation, extraperitoneal or intraperitoneal, the stump is a source of most of the danger."—JONES.

"All will agree that the pedicle is a source of danger, it matters not where it may be placed."—CROFFORD.

"What is the good of preserving the stump intraperitoneally or extraperitoneally? It can be of no service, but may do much damage."—JONES.

"Just what good this cervical stump can do when left I am unable to appreciate, and just what harm would accrue from its total ablation I am unable to divine."—CROFFORD.

I then give in order the following reasons why the stump should be removed, Dr. Crofford gives in order the advantages; and, by a singular coincidence, the four "reasons" and four "advantages" have a great similarity, and even corresponding numbers.

1. "Removing the stump very much shortens the operation."—JONES.

1. "It takes less time to do the operation."—CROFFORD.

2. "There will be less shock. Certainly to cut through such an organ as the uterus causes more profound shock than severing the vaginal membrane."—JONES.

2. "There is less shock after cutting vaginal than after cutting uterine tissue."—CROFFORD.

3. "This mode would very much lessen the danger of the operation, principally that it gets clear of the stump, '*et toutes ses douleurs.*'"—JONES.

3. "It does not leave a stump that predisposes to hemorrhage or infection."—CROFFORD.

4. "The patient would make a more rapid recovery."—JONES.

4. "It does not give a protracted convalescence."—CROFFORD.

Dr. Crofford adds as a fifth advantage, that "the removal of the cervix does not leave a weakened abdominal wall." On this point I am sorry to have to disagree with Dr. Crofford, for, whenever laparotomy is performed the abdominal walls are necessarily weakened, and consequently must give more or less danger or liability to hernia. Dr. Joseph Price, of Philadelphia, says: "Hernia cannot always be avoided, even by the most careful. They are, therefore, excluded from the avoidable sequelæ."[1]

Conclusion.—Our great object in trying or studying any method is to diminish the dangers of the operation and lessen the suffering of the patient.

ON THE RENEWED EMPLOYMENT OF THE NASAL DOUCHE AND KINDRED PROCEDURES.[2]

BY ALBERT H. BUCK, M.D.,

CLINICAL PROFESSOR OF THE DISEASES OF THE EAR, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK; CONSULTING SURGEON, NEW YORK EYE AND EAR INFIRMARY.

SEVERAL years ago Dr. Roosa, of this city, published an article in which he warned his medical brethren that the use of Weber's nasal douche could not be considered as an entirely harmless therapeutic procedure. He narrated a number of instances in which more or less serious inflammation of one or both middle ears had followed the use of the douche; and at a later date several other writers, myself among the number, reported many additional cases. It was observed also that other kindred procedures, like snuffing up fluids through the nasal passages, syringing these cavities either from in front or from behind, etc., were at times followed by the same aural inflammation. For a period of several years it seemed as if these warnings had been generally heeded, for, in my own practice at least, cases of inflammation of the middle ear following the use of some one of the procedures referred to above, became noticeably less frequent during this period. Now, however, the frequency of this class of cases is again decidedly on the increase. During the past winter and spring I have seen a larger number of them than at any previous period of my practice, and I thought it might not be amiss if I were to call attention once more to the harmful results which occasionally follow the use of the nasal douche and similar procedures.

As was also the case in former years, the favorite remedy in these recent cases seems to have been a weak solution of salt in water. In a few instances the resulting inflammation of the ear was very severe, but in the majority there was simply an increase of the subacute nasal and aural catarrh, for the relief of which the nasal douche or the snuffing method had been prescribed. In a small group of cases the aggravation of the aural symptoms seemed to owe its origin to the frequent use of Dobell's solution in the form of a nasal spray.

The question, How frequently do these aural complications arise in cases in which such therapeutic methods are used? is one which I am unable to answer. In the first place, I never use these methods in my practice, and consequently I am unable to say from personal experience how often the ear becomes involved; and when I ask my friends who devote their attention specially to nose and throat affections, and who are in the habit of prescribing the use of the douche, they uniformly answer that aural complications are exceedingly rare—so rare, in fact, that they have no hesitation in continuing to use these methods and remedies. I am at a loss to know how to harmonize these favorable reports with the frequency with which such cases present themselves for treatment in my own practice.

The question which would most naturally be asked of me in connection with this matter is, What safer and yet equally efficient plan of treatment would you recommend to take the place of those which you characterize as objectionable? I reply that, except in a single particular, the objects sought to be attained by these ob-

[1] Medical News, May 31, 1890.

jectionable procedures may be equally well secured by the free use, in the form of a spray, of such fluid mixtures as

℞. Eucalyptol and oil of wintergreen, each... gr. j.
Menthol..... gr. ij.
Benzoinol..... ʒ ij.
M.

Or, if the patient dislikes an oily preparation, the following may be prescribed:

℞. Listerine..... one part.
Water..... three parts.
M.

In the presence of an accumulation of viscid mucus or of crusts, a stream of flowing water will doubtless be found a more effective cleansing agent than a stimulating spray; but it is only in this respect that I can perceive any superiority of the douche over the sprays formulated above. Furthermore, if the latter are used freely—that is, several times a day, and each time during the inhalation (by the patient) of a deep breath, with closed mouth, crusts and tough mucus will speedily cease to play a part in the therapeutic problem.

In not a single instance have I known the freest introduction of the mixtures named to be accompanied by any unpleasant aural symptoms. The immediate effects are very gratifying to the patient, and in a brief time a permanent diminution of the nasal and naso-pharyngeal irritation can generally be noted. The use of sprays, however, must be looked upon only as a valuable method of supplementary treatment, and not as a therapeutic procedure of the first order The removal of hypertrophied glandular tissue and the local application of silver nitrate are the only remedial measures that are at all worthy of being considered fundamentally curative of the conditions which usually lead the physician to prescribe the use of the nasal douche or one of its substitutes.

TWO CASES OF MALIGNANT DISEASE OF THE PHARYNGO-LARYNX AND LARYNX.

By J. MORRISON RAY, M.D.,

SURGEON TO THE EYE, EAR, AND THROAT DEPARTMENT OF STS. MARY AND ELIZABETH AND LOUISVILLE CITY HOSPITALS.

CANCEROUS disease of the lower pharynx and larynx is sufficiently uncommon to permit the report of two cases. These presented points of interest in their history and progress—not the least important of which was the extent of disease present when medical care was sought, and the rapidly fatal termination in each.

CASE I.—Thomas L——, aged thirty-six, Englishman, dog-trainer, came under observation at the Louisville City Hospital, March 1, 1888. He was a man of good physique, only slightly emaciated, with much difficulty in breathing, and aphonic. The dyspnœa was so great that Dr. Vance, in charge of the surgical wards, was asked to see the case at once with the intention of performing tracheotomy. On my examining with the laryngeal mirror, the upper portion of the larynx was found to be filled with a large, irregular, warty mass, covered with mucus and pus. The pyriform fossa was filled with the growth, the epiglottis pushed far to the left and its right free edge involved. The chink of the glottis was overhung by the tumor. From the great effort required in breathing and the narrow space left through which air could enter, an immediate tracheotomy was demanded. This was performed by Dr. Vance under local hypodermic injections of cocaine. The relief from dyspnœa following introduction of the tracheotomy-tube was immediate. In a short time quiet sleep was procured. The next day he appeared bright and was breathing easily. The following history was obtained. He had suffered with some throat trouble for two months. The hoarseness increased rapidly, and for about two weeks there had been progressive difficulty in breathing. There had been no great trouble in swallowing until within a few days. No enlargement of the lymphatic glands in the neck, and no pain in the ear, or hemorrhage. The relief following the tracheotomy lasted only for three days, when respiration again became labored, and notwithstanding the introduction of a longer tube, he died on the sixth day with exhaustion from labored respiration.

The larynx and trachea, with the tongue attached, were removed by one of the internes. On longitudinal section a growth was found involving the entire right half of the larynx, extending on to the epiglottis. Below the lower edge of the growth the trachea was enlarged to nearly twice its normal calibre. The tissues surrounding the tracheotomy orifice were necrotic, but the orifice was not encroached upon by the neoplasm. Dr. Simon Flexner kindly examined the growth microscopically, and reported that "it presented all the features of a typical squamous celled epithelioma. Notwithstanding its rapid proliferation, the cellular elements were well formed and the cell-nests numerous, large, and strikingly perfect."

The local appearance of this tumor, when viewed through the laryngeal mirror, was that of an epithelioma, but the age, absence of glandular enlargement, hemorrhage, and only slight pain on swallowing led to the belief that it was a sarcomatous growth.

Epithelioma are the most frequently encountered of all growths in this locality. In Mackenzie's report of 53 cases of malignant growth involving the larynx proper, 45 were epithelioma. Of these only 6 occurred between the ages of thirty and forty. The question of extirpation was never considered in this case, since the tracheotomy did not prolong life as much as had been expected. Had the case been seen earlier in its progress and its nature recognized, tracheotomy, followed by extirpation of the right half of the larynx, might have added several years to his life. Mackenzie states that the average duration of life in epithelioma of the larynx is from eighteen months to two years. It is remarkable in this case for the growth to have existed so long and only within two months given rise to symptoms referable to the throat. The cartilaginous framework of the larynx was not involved in the growth.

CASE II.—Dr. ——, retired physician, consulted me through the request of Dr. E. R. Palmer, in May, 1889. He had formerly lived in Kentucky, but for the past fifteen years had been a resident of Florida. Several years ago he had much trouble from recurring tonsillitis, but since his residence in the warm southern climate this had disappeared. In January, 1889, he began to expectorate considerable mucus, and he noticed an enlargement of one of the lymphatic glands beneath the angle of the jaw on the right side. When a young man he contracted syphilis, but underwent prolonged treatment, and had not in forty years noticed symptoms of the disease. The throat annoyance has gradually increased, and coming to Kentucky on business, he concluded to seek advice. He appeared somewhat exhausted, as he explained, from long travel, was always a man of slight flesh; nevertheless he had been strong before starting on his journey. His voice was clear, his swallowing was not painful, but very deliberate. Had suffered at times with darting pains in the right side of the neck, extending up to the ear. Breathing was free. On examination I found nothing in the oro-pharynx. With the laryngeal mirror a mass was seen projecting from the right lateral wall of the pharynx above the entrance into the larynx. It was covered with pus, and was about three-fourths of an inch long and one-half of an inch in width, and protruded so as to interfere with the epiglottis during the act of deglutition. The lymphatic glands on right side of the neck are enlarged. The larynx could be seen, and no growth extending into it was discovered; yet the right half was partially fixed and the opposite vocal cord in its excursions passed beyond the middle line to the right. There was no family history of cancer. His father died at an advanced age and his mother still lives. The brothers and sisters that

died had succumbed to acute diseases, three still living and healthy. One week after my first examination he was seen in consultation by Dr. Coomes, and with his assistance I removed with the laryngeal forceps a piece of the growth that made up about one-third of the projecting mass. In a few days another attempt was made, and the growth removed almost to a level with the walls of the pharynx. After these operations the glandular infiltration in the neck rapidly increased. Dr. D. W. Yandell was consulted as to the advisability of an operation from without, but he advised against external interference. The patient was also presented to the Medico Chirurgical Society, and the question of a radical operation discussed, but the majority of opinion was averse to such proceeding. The growth soon again became prominent in the throat, and interfered with deglutition by obstructing the epiglottis. The right arytenoid prominence became boggy and infiltrated, and the right cord fixed. Another operation with forceps and galvano-cautery was resorted to, after which deglutition was easier, but the glands in the neck rapidly enlarged after the operation, and extended from the parotid gland to the clavicle. They were very hard and growing more painful. August 1st he began to show well-marked signs of the cancerous cachexia, and soon went to the home of his family in this State, where he died August 30th from exhaustion, without signs of obstructed respiration. No autopsy. The pieces removed with the forceps at two different sittings were submitted to Dr. Simon Flexner for microscopical examination. He reported that "the portion removed at the first operation showed many embryonic elements and but few epithelial cells, with a total absence of alveolar structure. The pieces removed subsequently presented the appearance of typical encephaloid carcinoma. It seems that the first tissue examined was from the margin of the spreading growth and consisted of the so-called indifferent tissue, the precursor of carcinomatous invasion."

When this case was first seen and the history obtained, it was thought that it might be specific, and to clear up this doubt potass. iodide was given in increasing doses, but without effect. Later on, under the recommendation of Baratoux, the tincture thuja occidentalis (arbor vitæ) internally and locally was tried, but without effect on the rapidity of the extension or the excessive secretion, which had become a great annoyance.

Again, in this case the rapidity of the growth is at variance with the teachings of Mackenzie. He says the duration of life in encephaloid is three years. As to the frequency of growths in this locality, Lenox Browne says they are rare, but when present are usually encephaloid.

Remarks.—These two cases present different varieties of cancerous involvement of contiguous parts. One in a man thirty-six years of age, the other in a man of fifty-nine. They ran a much more rapidly fatal course than, from the writings of others, we had been led to consider. In neither case was there a history of hemorrhage or great pain until the last, at which time the second case required large doses of morphine to control the lancinating pains on the side of the neck, ear, and head. In both cases the growth was on the right side. Fauvel states that from his observation the majority of malignant growths primarily in the throat are on the left side. Glandular infiltration in the neck was present in the case where the growth originated in the lower pharynx. In the other, where the larynx was the seat of the growth, at no time was there discovered gland enlargement. This observation is in accord with the statement of Krishaber, in that extrinsic cancer of the larynx (pharyngo-larynx) very early in its course produces glandular infiltration, while intrinsic cancer rarely induces cervical gland enlargement. In the case where gland enlargement was present it eventually became the most annoying symptom, since it gave rise through pressure to intense pain. After each attempt at endo-pharyngeal removal the glands became rapidly larger. Newman, of Glasgow, has recently noticed the same effect, and therefore argues that on this account operations for removal through the mouth must not be attempted, but the growth should be removed by an operation from without. From careful observation of these two cases, I am led to believe that malignant diseases involving these parts are much earlier fatal than we are led to believe. Therefore, any method to be resorted to for their eradication must be done early, thoroughly, and, preferably, by external incision.

419 West Chestnut Street, Louisville, Ky.

Progress of Medical Science.

Primary Cerebral Sclerosis in Children.—Richardière says: 1. There are several forms of primary cerebral sclerosis in children. 2. Of these there are two which are especially prominent: (*a*) A sclerosis of a whole hemisphere or of an entire lobe; (*b*) a sclerosis which occurs in distributed tuberosities on the surface of the convolutions. 3. The first form extends over a large surface of the brain-substance and produces the atrophic sclerosis. 4. The second form produces elevated nodules and increases the cerebral substance forming the hypertrophic sclerosis. 5. The atrophic form is characterized anatomically by diminution of the volume and hardening of the convolutions; histologically, by the development of connective tissue, dilatation of the blood-vessels, and atrophy of the nerve-elements. 6. The nodules of the hypertrophic form are made up of connective tissue. 7. The starting-point of these lesions seems to be the vessels. The atrophic lobular sclerosis seems particularly to be an arterial sclerosis. 8. Primary cerebral sclerosis occurs in children between the third and fifth year. Its nature is obscure, although it sometimes follows the infectious diseases. 9. The atrophic sclerosis manifests itself by convulsions, epileptic attacks, paralysis, and contractures, which are of long duration. 10. The symptoms of hypertrophic sclerosis are almost identical, but the change in the intelligence is less marked, and the paralytic phenomena more discriminated. The symptoms are not of such long duration. 11. The prognosis in reference to the intelligence and motility of the children is an unfavorable one. 12. The diagnosis is not difficult when we can exclude hemorrhage and brain diseases, which lead of themselves to atrophy.—*New York Medical Journal.*

Hypogastric Puncture of the Bladder.—Dr. Deneffe says that too serious a view is taken of hypogastric puncture of the bladder in cases of retention. It ought not to be considered as dangerous, and as a last resource. He quotes a case of hypertrophied prostate which prevented micturition and catheterism, in which the patient was punctured seventeen times without suffering any inconvenience. The seventeenth time, the trocar was allowed to remain, and ten days afterward micturition took place spontaneously through the urethra. Nevertheless, the trocar was allowed to remain twenty-nine days, when it was removed. The fistula was closed in four days, and the patient recovered permanently.

Hypogastric puncture is considered a mild operation by Dr. Deneffe, and he states that he has performed the operation on three hundred and one patients, with a mortality of only two and a half per cent. A patient suffering from enlarged prostate or stricture suddenly cannot micturate, and this is usually due to a sudden spasm of the posterior portion of the urethra being superadded to the original lesion. Catheterism is not adapted to reduce a spasmodic contraction, and the urethra affected by spasm can only be benefited by the contact of irritating urine being removed.—*Journal de Médecine de Paris.*

Death of Professor Neugebauer.—Dr. Neugebauer, the well-known gynecologist of Warsaw, died while attending the Medical Congress at Berlin.

DISEASED CRAVINGS AND PARALYZED CONTROL.

IN a series of interesting articles in the *Edinburgh Medical Journal*, December, 1889, to May, 1890, Dr. Clouston discusses this important and difficult subject in its general aspects, and adds his views, to which we cannot now particularly refer, in regard to the peculiar characteristics of each of the prominent drug habits.

Desires are but the indications of the needs of the organism. In a perfectly healthy man all his desires and cravings can as a rule be gratified in some proper way at some proper time, so as to promote the good of body and mind, none requiring absolute inhibition. The proper time and way to gratify them is determined by the controlling influence of reason, experience, and law. A craving which leads to harm is a diseased craving.

The strongest and most subtile desires of man arise in the highest centres of the cerebral cortex—in the emotional centres, and are not necessarily connected with any functional activity of the lower nervous centres, as the sympathetic or visceral ganglia.

The impulses which guide and regulate these desires must also proceed from the highest cerebral regions. They are not purely of a spiritual nature, but are associated directly with physical changes in the brain-tissue. The waste of substance which occurs during the exercise of such inhibition is evidenced by the feeling of fatigue and the circulatory changes which follow any prolonged attempt to direct or to restrain the desires.

For the manifestation of hurtful desires there must be present a diseased craving, and also a paralysis of control.

The peculiar work that the nerve-cell must do requires that it should be not sluggish and stable, but sensitive and unstable. In certain individuals this sensitiveness and instability are carried to excess and the cell acts in an explosive manner. In a motor cell this abnormal condition gives rise to convulsions and exaggerated reflexes; in an emotional centre, it causes explosions of passion and diseased cravings. A tendency to this emotional condition is obtained by heredity from ancestors whose brains have been subjected to undue excitement or have been poisoned by alcohol, opium, or syphilis.

Such brain-cells, when fatigued by their own excessive action, which is frequently out of all proportion to the strength of the body, excite an intense craving for restorative agents. Now, recuperation through rest and food is a slow process, and very irksome to many individuals. They find in alcohol and certain other drugs something which has a special affinity for these tired nerve-cells, which produces a rapid and pleasurable relief to the sense of fatigue, enabling them to continue their immoderate activities without the refreshment and rest which is really needed. The result is that, when the influence of the drug is gone, a double weakness is felt and an increased temptation to resort to the drug, moreover, as Dr. Clouston expresses it, a "memory" of the craving for the drug continues for a long time, and may even be handed down to posterity as a quality of the fœtal nerve-cell.

Inhibition or control over the emotions and over conduct is the highest function of the human brain. Among savages and persons of little culture control may be very feeble in regard to some emotions and very strongly developed in regard to others. In the child control of the emotions is gradually developed, and that more rapidly in some than in others. The power to do the right and refrain from the wrong is earliest seen in a good stock. This power is slow in development, or may never become strong, in the children of habitual criminals, drunkards, and insane persons. The power of inhibition and control may, even in the best stock, be destroyed by alcoholic poisoning.

Just as diseased cravings may occur without paralysis of control, the cravings being kept in check by the will, so paralysis of control may exist without the occurrence of diseased cravings, the patient, though destitute of the power to resist evil suggestions from without, like a person hypnotized, yet passing through this diseased state into convalescence without doing anything amiss, requiring only a little wise guidance from the attendant. In most cases, however, diseased cravings and paralyzed control occur together, although it is not easy to see why the one should involve the other.

In conclusion, the coexistence of these states may arise from or accompany: 1, Inherited feebleness of brain power; 2, neurotic states in adolescence; 3, continued dissipation; 4, excessive mental strain; 5, lack of education in right ways; 6, want of needed mental stimulation, as from social intercourse; 7, physiological strains, as menstruation, in persons of nervous temperaments; 8, insanity, as a complication; 9, insanity, as an alternative state; 10, gross brain disease, as from injuries; 11, senile brain degeneration; 12, disease of parts other than the nervous system, as a complication.

SALOL IN ACUTE TONSILLITIS AND PHARYNGITIS.

FEW diseases are more prevalent in our climate than acute angina. And while attacks of tonsillitis and pharyngitis are not to be classed with the graver affections, the amount of suffering and discomfort they entail often make them objects of serious concern to the practitioner. These inflammations are strictly self-limited, and generally subside without treatment in from three to seven days. Nevertheless, the means at our command to lessen the annoying dysphagia and other distressing symptoms are not as satisfactory as they might be, especially from the patient's point of view.

Salol has lately received some warm praises as a drug

that can be relied upon to favorably influence the course of these affections. Gouguenheim and Capart have pointed out its utility, and in our country Dr. Jonathan Wright, of Brooklyn (*The American Journal of the Medical Sciences*, August, 1890), speaks highly of the remedy. As salol is one of our newer compounds, Dr. Wright's brief synopsis of its properties and action may serve as a reminder here.

It was discovered by Nencki, a Swiss chemist, in 1883, and first used by Sahli in 1886. It is a colorless substance, sold in the shops as a coarse, white crystalline powder. It has a marked aromatic odor, and a faint taste, which is rather agreeable than otherwise. Chemically it consists of salicylic acid in which one atom of hydrogen has been replaced by the phenol group, and contains synthetically forty per cent. of the latter and sixty per cent. of the former. It is a proprietary article, made abroad, and usually sells at four dollars a pound.

It is insoluble in water, but, like the fats, is soluble in alcohol and ether, and is decomposed by sodium bicarbonate. Hence it should not be given in combination with the latter. It forms emulsions easily. Though crystalline in structure, it cannot be reduced to a fine powder, on account of the tendency of its particles to cohere. It has a low melting-point (43° C.).

It is insoluble in the gastric juice, but is readily dissolved in the pancreatic and intestinal secretions, where it is separated into its primary constituents, both of which are readily absorbed and appear in the urine, giving it the olive-green color caused by carbolic acid. In thirty-grain doses it is a powerful antipyretic, but in smaller and frequently repeated doses (five grains every hour) it is not so efficient in this regard. Its odor is very distinctly appreciated in the secretions and in the expired air.

The unique characteristic of salol in being able to pass the gastric juice unchanged, while in the intestines it is decomposed into phenol and salicylic acid, both being antiseptics, has been taken advantage of in treating the summer diarrhœas of children. The rapidity with which these drugs are absorbed, and the promptness with which they appear in the urine, have made it valuable in treating cystitis, pyelitis, and gonorrhœa.

It has been used as an antipyretic successfully. But its principal use has been as a substitute for the compounds of salicylic acid in the treatment of rheumatism.

It has proved of service in sciatica and lumbago.

The observations on its effects in allaying the pain in rheumatism are interesting in a consideration of its action on the dysphagia of acute throat affections, the time in which it is said to relieve the pain—twenty-four to forty-eight hours—corresponding very closely to the author's experience. Its occasional entire failure is also noted in both cases. The carboluria, which is always present, is the only sign of any phenol poisoning that is noticed, and need consequently give rise to no apprehensions.

In its administration he has never given less than sixty grains daily, nor more than one hundred and twenty, the most frequent dose having been ninety grains for adults. It may be given in powder form or as an emulsion. The most efficient method is to give it in ten-grain doses every two hours during the day.

He has noticed the most marked effect in lacunar tonsillitis, less in catarrhal pharyngitis, and least in a well-developed quinsy. For the latter, hot fomentations and free incision are the best remedies, though salol may be given as an adjuvant. This, of course, only applies to cases after the fourth day, before that time the greatest relief being often obtainable by the use of the drug.

Dr. Wright concludes by transcribing Gouguenheim's summary, which he indorses in every particular:

1. Salol acts beneficially in acute anginas of whatever cause.
2. It quiets the pain and dysphagia with the greatest rapidity.
3. In quieting the pain it may shorten the duration of quinsy.
4. It lowers the temperature.
5. In nearly all cases it diminishes the duration of the angina.
6. In order to attain these results, the dose should not be less than sixty grains daily.

THE KNEE-CHEST POSTURE IN THE CORRECTION OF SHOULDER PRESENTATIONS.

To the superficial observer it may seem that the field of every-day practical medicine has been so often worked over by industrious text-book writers that there is nothing left for the average doctor but to follow reverently and contentedly their infallible teachings. Now and then, however, the profession is startled by most unexpected and important discoveries in some obscure or neglected nook or corner, or by some valuable improvement upon the methods of the sages which is accidentally hit upon. Occasionally some new method of practice will be discovered, and reported again and again by solitary workers for years before it is adopted by the standard authors and incorporated into the general body of professional knowledge.

A striking illustration of this fact is given by Dr. Wells (*American Journal of Obstetrics*, March, 1890, p. 286) in an article upon "Shoulder Presentations," in which he gives the history of the employment of the knee-chest posture in the correction of the malposition of the fœtus. It seems that this method was recommended as far back as in the beginning of the Christian era and that it was taught by various writers in the eighteenth century. That it has of late been forgotten or fallen into disrepute is possibly due to the ease with which versions can be done under chloroform or ether in the ordinary obstetric position.

It seems that in many cases, if not in all, in which the method was applied by one who had not been taught it, the knee-chest or knee-elbow position had been used, not with a direct view to the facilitation of version, but in order to moderate the excessive and dangerous contractions of the uterus or for the purpose of allowing a prolapsed umbilical cord to recede into the cavity of the uterus. When the posture had been assumed, the obstetrician found to his surprise and delight not only that the original object was secured but that correction of the malposition of the child's body was rendered very easy on account of the relaxation of abdominal and uterine pressure upon the child's body, and, through it, upon the lower segment of the uterus.

When the usefulness of this posture has once been established it is easy to see how valuable may be its applications in abnormal presentations of all sorts. It may be used for reposition of the prolapsed cord, for correction of transverse presentations of side, shoulder, or hand, for relief of impacted parts—as shoulder, or head, and for the prevention of painful bruising of the lower segment of the uterus between the head and the pelvic brim. As has been suggested, many of these ends are now usually secured with ease by the induction of anæsthesia, but under certain conditions it may happen that anæsthesia fails or cannot be used, and in some cases it may be wise to make use of both anæsthesia and posture, in spite of the possible increase in danger from anæsthetizing in the knee-chest position, or perhaps in "Sims' position."

But, to return to the treatment of shoulder presentations. If the physician is summoned early to the case, and diagnoses this presentation, it is usually advisable to delay until the os is well dilated or easily dilatable. The patient is then placed upon her knees and chest or in any other position that will swing the uterus forward and away from its vaginal attachment. The hand is then introduced, the membranes are ruptured if still intact, and by pressure upon the shoulder from within, and upon the breech or head from without, the shoulder is pushed from the os, and the head is made to replace it. The woman is now raised upright upon her knees and supported in this posture until the head becomes fixed in its new position by a pain, and the woman is then allowed to lie in the customary position while the labor proceeds as a simple head-first case. In some instances the head cannot be brought to engage at the os and then the shoulder must be pushed in the opposite direction until the breech engages or a foot is brought down. In bringing the head or breech to the os, the fingers or hands need not penetrate deeply into the uterus, but in seeking the feet they must pass far in, as the long diameter of the uterus is increased by the posture of the woman.

The suggestions of Dr. Wells in this article are valuable as an important contribution to current methods. To what extent this method will supplant that of correction in the dorsal position under chloroform remains to be seen. It is more in accordance with present views that correction of the malposition should be made without rupture of the membranes. If the membranes have been broken, too, the knee-chest position is more favorable than the dorsal position to the entrance of air into the cavity from which the waters have escaped, an accident which may lead to the death of the child unless speedy delivery follows.

Hypnotism at a Revival Meeting.—A female revivalist has been conducting a series of meetings in St. Louis and has met with great success, her converts being numbered by the hundreds. Many of the latter have visions while under religious excitement, and some physicians have called on the authorities to prohibit the meetings, upon the ground that the converts are hypnotized. The complainants say that the revivalist is herself insane, and that the influence she exerts upon her hypnotized converts is exceedingly harmful, and they therefore ask the mayor to stop the proceedings on account of the injury to public health of which they are the cause.

News of the Week.

A Medical Candidate.—Dr. Alexander Bear, of Norfolk, Neb., is a nominee for Lieutenant-Governor of the State. Dr. Bear was born in Virginia, and is now about fifty years of age. He was a member of the State Legislature, occupying a seat in the Senate in the sessions of 1872 and 1873; also as a member of the House in 1876. He held the position of Regent of the State University from the year 1874 to 1880.

A New Hospital in Brooklyn.—The German Hospital Association was organized in Brooklyn about a year ago, the object being to establish a German hospital in that city. At a recent meeting it was announced that the Association had purchased twenty-seven building lots on Stanhope and Stockholm Streets, between Wyckoff and St. Nicholas Avenues, in the Eighteenth Ward, which were free and clear of all incumbrances, for a site for the new building. The name of the new institution will be the German Hospital of Brooklyn. Besides the usual accommodations for the sick, it is intended to set a part of the building aside for well-lighted and ventilated lecture-rooms; a chemical laboratory, fitted up with the latest improvements, and another devoted to histological researches; a number of recitation and operating rooms, and a suite of chambers intended for the private use of the members of the hospital staff.

Hypnotism in Russia.—The Russian Government has recently forbidden public *séances* of hypnotism, and the application of it to the treatment of disease is only allowed in the presence of several medical men.

Insanity in England.—The report of the English commissioners in lunacy states that the total number of lunatics, idiots, and persons of unsound mind under official cognizance in England and Wales on January 1st last was 86,067, being an increase of 1,727 as compared with January 1, 1889.

The New Surgeon-General of the United States Army.—The President has sent to the Senate the nomination of Colonel Jedediah H. Baxter, Chief Medical Purveyor, to be Surgeon-General of the Army. The appointment comes in the natural line of promotion, since he is the senior next in rank to the retiring officer whose place he is to fill. Dr. Baxter entered the military service in June, 1861, as Surgeon of the Twelfth Massachusetts Infantry. In April, 1862, he was transferred to the United States Volunteers, and at the close of the war entered the regular service with the brevet rank of colonel. In July, 1867, he was appointed Assistant Medical Purveyor, with the rank of lieutenant-colonel, and five years later was promoted to be Chief Medical Purveyor, receiving at the same time a colonelcy, and has held that office and rank ever since. The records of the department contain numerous references to Dr. Baxter's faithful and meritorious services, both during and since the war.

Unhealthy Schools in Philadelphia.—The sanitary committee of the Philadelphia Board of Health has been investigating the condition of the school houses in that city, and recently presented its report, showing that up ward of sixteen schools had been found to be in a more or less unsanitary state.

The Tri-State Medical Association will commence its second annual meeting in Chattanooga, Tenn., on Tuesday, October 14, 1890, continuing in session three days.

The American Association of Obstetricians and Gynecologists will hold its next annual meeting in the city of Philadelphia, on Tuesday, Wednesday, and Thursday, September 16, 17, and 18, 1890, in the hall of the College of Physicians, corner of Thirteenth and Locust Streets. All physicians interested are invited to attend the several sessions. Dr. William Warren Potter is Secretary and Dr. E. E. Montgomery President of the Association.

A Gift to a Medical College Questioned.—The relatives of Dr. Lomax, of Mattoon, Ind., are about to contest his bequest of his entire estate to the Indiana Medical College. The transfer of the property is by deed, and not by will, and the Medical College people are confident that they can retain possession of the gift.

The American Rhinological Association will hold its eighth annual session at Louisville, Ky., October 6th, 7th, and 8th. All leading subjects relating to nasal and naso-pharyngeal diseases will be opened for discussion by a leading fellow of the Association. The medical profession is cordially invited to attend. The Secretary, Dr. R. S. Knode, Omaha, Neb., will furnish any information to physicians desiring to become members.

Translation of Fränkel's Work.—Dr. J. H. Linsley, of this city, is engaged in the translation of Fränkel's recently published work on bacteriology.

Adoption of the Decimal System in Russia.—The Russian Government has ordered that all medical and pharmaceutical students shall be henceforth accustomed to the decimal system of weights and measures, with the view of making this system the only legal one for prescriptions to be written in after the lapse of five years, as it is intended to abolish altogether the use of the so-called Nurnberg weights, which are still in very general use in prescribing and dispensing. Soon Great Britain and the United States will be the only civilized countries on the globe where the old system of weights and measures is in use. It is strange that in this country, where decimal coinage has always existed, the adoption of the decimal weights and measures used by the rest of the world should be so long delayed.

American Orthopedic Association.—The following is the programme of the fourth annual meeting of this association, to be held in Philadelphia, September 16–18, 1890:

Tuesday, September 16th.—Business meeting for the appointment of committees, etc. Address by the President on "Spinal Distortions and their Treatment by the Straitened Leather Jacket," by Dr. Bernard Bartow, of Buffalo; "Treatment of Deformities of Spastic Paralysis," by Dr. E. H. Bradford, of Boston; "Tenotomy for Relief of Deformity in Spastic Paralysis," by Dr. Arthur J. Gillette, of St. Paul; "Amputation as an Orthopedic Measure," by Dr. Ap Morgan Vance, of Louisville; "A Ready Method of Counter-traction at the Knee," by Dr. Henry Ling Taylor, of New York; "Treatment of Infantile Club-foot Preliminary to Operation," by Dr. F. H. Milliken, of New York (by invitation); "Paralytic Club-foot," by Dr. W. R. Townsend, of New York; "Ten Years' Experience in the Management of Knee-joint Disease," by Dr. V. P. Gibney, of New York; "The Inefficiency of Mechanical Treatment in Spasmodic Wry-neck, with a Report of Three Cases," by Dr. George W. Ryan, of Cincinnati; "Sacro-iliac Disease," by Dr. Benjamin Lee, of Philadelphia; "Instantaneous Photographs Illustrating the Gait of a Child from whom both Hips had been removed," by Dr. H. M. Sherman, of San Francisco.

Wednesday, September 17th.—This day will be devoted to the subject of "Rotary Curvature of the Spine," when the following papers will be read: "The Nervous and Muscular Elements in the Causation of Idiopathic Curvature," by Dr. Benjamin Lee; "The Muscular Element in the Etiology," by Dr. Charles L. Scudder; "Etiology," by Dr. R. W. Lovett; "Mechanism of Rotation," by Dr. A. B. Judson; "The Mechanical Theory," by Dr. O. H. Allis (by invitation); "Causes," by Dr. M. T. Bissel (by invitation); "Pathogeny," by Dr. Newton M. Shaffer; "Treatment Especially Applicable to Poor and Dispensary Patients," by Dr. V. P. Gibney; "Treatment," by Drs. E. H. Bradford, B. E. McKenzie, and Henry Ling Taylor.

Thursday, September 18th.—"The Significance and Value of Involuntary Muscular Protection, and the Limp of the First Apparent Stage of Hip Disease," by Dr. Newton M. Shaffer, of New York; "Treatment of Hip Disease," by Dr. B. E. McKenzie, of Toronto; "A Report of Sixty-two Cases of Hip Disease Observed in the Practice of Hugh Owen Thomas," by Dr. John Ridlon, of New York; "Diseases of the Eye Associated with Spinal Caries," by Dr. James K. Young, of Philadelphia (by invitation); "Posterior Rachitic Curvature of the Spine," by Dr. Samuel Ketch, of New York; "Lateral Deviation of the Spinal Column in Pott's Disease," by Dr. R. W. Lovett, of Boston; "Relief of Paraplegia," by Dr. A. J. Steele, of St. Louis; "Prognosis of Pressure Paralysis," by Dr. T. Halsted Myers, of New York; "Do Orthopedic Surgeons Operate as Frequently as they Should?" by Dr. J. E. Moore, of Minneapolis; "Joint Diseases," by Dr. John Ridlon, of New York; Papers (titles not sent), by Drs. T. G. Morton, Roswell Park, R. H. Sayre, and H. A. Wilson.

The papers will be discussed by the following gentlemen: "Lateral Curvature," by Dr. George W. Ryan; "Deformities of Spastic Paralysis," by Dr. Roswell Park; "Amputation as an Orthopedic Measure," by Dr. L. A. Sayre, Dr. A. J. Gillette; "Ready Method of Counter-traction at the Knee," by Dr. R. H. Sayre; "Paralytic Club-foot," by Dr. H. Hodgen; "Treatment of Infantile Club-foot Preliminary to Operation," by Dr. J. C. Schaaps; "Ten Years' Experience in the Management of Knee-joint Disease," by Dr. Joseph D. Bryant, Dr. George B. Packard; "Treatment of Hip Disease," by Dr. J. E. Moore; "Value of Muscular Protection and the Limp of the First Stage of Hip Disease," by Dr. C. C. Foster; "Joint Diseases," by Dr. W. R. Whitehead; "Diseases of the Eye Associated with Spinal Caries," by Dr. H. E. Goodman; "Prognosis of Pressure Paralysis," by Dr. C. L. Scudder; "The Relief of Paraplegia," by Dr. C. W. Stimson; "Lateral Deviation of the Spinal Column in Pott's Disease," by Dr. Dillon Brown; "Posterior Rachitic Curvature of the Spine," by Dr. E. G. Brackett; "Sacro-iliac Disease," by Dr. L. A. Weigel; "Instantaneous Photographs, Illustrating the Gait of a Child from whom both Hips had been Removed," by Dr. George S. Knickerbocker.

Society Reports.

TENTH INTERNATIONAL MEDICAL CONGRESS.

Held in Berlin, August 4, 5, 6, 7, 8, *and* 9, 1890.

(Special Report for the Medical Record.)

(Continued from page 252.)

SECTION ON OBSTETRICS AND GYNECOLOGY.

FIRST DAY, MONDAY, AUGUST 4TH.

President's Address. — DR. A. MARTIN, of Berlin, opened the first session with a few words of welcome, in which he congratulated the members on the prospect of a brilliant meeting. There was, however, an embarrassment of riches in the way of papers, and it would be necessary to be very saving of time. He suggested that the time allowed for each paper be reduced from twenty minutes to ten, and that for the discussions from ten minutes to five. No objection being made, this rule was adopted.

Presiding Officers.—The following gentlemen were then elected to preside at the different meetings of the Section: Drs. Dohrn, of Königsberg, Halbertsma, of Utrecht, Péan, of Paris, Simpson, of Edinburgh, Parvin, of Philadelphia, Slavyansky, of St. Petersburg, Pasquali, of Rome, Stadfeldt, of Copenhagen, Chrobak, of Vienna, Fochier, of Lyons, Priestley, of London, Cushing, of San Francisco, and Winckel, of Munich.

Antisepsis in Midwifery.—DR. GALABIN, of London, had been appointed to open the discussion on this subject, but was prevented from attending and sent his paper, which was passed around in abstract among the members. He was an ardent believer in the efficacy of antisepsis, and insisted upon its being carried out with great thoroughness. The hands of the accoucheur and nurse, as well as the instruments used, should be rendered strictly aseptic, and vaginal injections of corrosive sublimate (1 to 2,000) should be freely employed.

DR. SLAVYANSKY, of St. Petersburg, read a paper on the same subject, giving an extended account of the success following the introduction of this method in Russia, in which country it was now universally observed. He had collected the reports of cases in over fifty institutions, and showed from them that the mortality among lying-in women had fallen from 0.48 per cent. in 1886 to 0.28 per cent. in 1889. The morbidity had also fallen, and was now but 6.9 per cent. He believed that, with strict attention to antisepsis, there was no more danger in large institutions than in small ones, and the former were to be preferred because of the educational facilities which they afforded. The presence of students need not be feared if only the antisepsis be carefully preserved.

DR. STADFELDT, of Copenhagen, said the introduction of antisepsis in midwifery had made it possible to turn the large lying-in institutions to account for teaching purposes without prejudice to the patients. Antisepsis was of great advantage to the new-born as well as to the women. In private practice midwives should keep their clothes, persons, and instruments thoroughly aseptic. They should not attend the woman after her confinement if she developed any puerperal disease. They should be careful to see that everything about the patient was rendered antiseptic, but he feared that vaginal injections in the hands of the ordinary midwife would be likely to prove more injurious than beneficial. Midwives ought also to abstain as far as possible during the progress of labor from making vaginal examinations. In case of puerperal disease developing, the health authorities ought to be at once notified, and should several cases of puerperal fever happen to arise in the practice of the same midwife, the latter must be forbidden to practise for a time.

DR. FRITSCH, of Breslau, thought that antisepsis had been overdone in the early days of its use in midwifery, but was glad to believe that there was at present much more moderation in its employment. He thought healthy women needed no local treatment, and even a mild grade of fever called for nothing more than watchfulness on the part of the attendant. In cases of very high temperature irrigation of the uterus was called for in conjunction with other treatment, though it could never be relied upon alone to reduce the temperature.

Bacteriology of the Vaginal Secretions.—DR. DOEDERLEIN, of Leipsic, had examined carefully the secretions from the vagina in lying-in women, and thought that the results were a strong argument in support of the necessity of antiseptic douches. He had learned to discriminate two varieties of secretion, one very acid and containing epithelial cells, granular corpuscles, and non-pathogenic bacteria. This was the normal secretion. The other variety of secretion was virulent, neutral, or alkaline in reaction, and contained globules of pus and micro-organisms of different forms, but especially cocci. In the first case no danger of infection through the vagina during labor is to be feared, but in the second most careful disinfection is urgently indicated.

DR. PRIESTLEY, of London, recalled the great mortality attending childbirth in certain institutions before the introduction of antisepsis, and thought that the change which had now taken place in this respect was argument enough in support of the measure. He was sorry, however, that Dr. Galabin had recommended douches of corrosive sublimate of the strength of one in two thousand, for he had seen serious results follow the use of such a strong solution. One to four thousand was, in his opinion, strong enough, and far safer.

SECOND DAY, TUESDAY, AUGUST 5TH.

Extra-uterine Pregnancy.—DR. LEOPOLD, of Dresden, presented a number of specimens illustrating various forms of ectopic gestation. One was a case of ovarian and another of tubal pregnancy, both carried to the ninth month without rupture. He also showed a lithopædion, resulting from ovarian pregnancy, and carried for twenty-five years before removal. Several others were cases in which rupture had taken place.

Frozen Sections from Labor at the Eighth Month.—DR. BARBOUR, of Edinburgh, showed some frozen sections and casts illustrating the progress of labor. One case was at the second stage with the child's head on the perineum, and showed the presence of a distinct retraction-ring. The muscular tissue above this ring was able to propel the fœtus, but when the latter had passed below this it was expelled by the action of the voluntary muscles. There was extension instead of flexion of the head of the fœtus.

Extirpation of the Uterus.—DR. OLSHAUSEN, of Berlin, reported several cases of extirpation of the uterus; one of these was for carcinoma, and although nine years had since elapsed, there had been no recurrence of the disease. He also showed a patient upon whom he had operated for tubal pregnancy, a living child being removed. Within a year the same woman became pregnant in the other tube, and was operated upon after the tube had ruptured.

Laparotomy during Pregnancy.—DR. CALDERINI, of Parma, reported three cases in which he had performed laparotomy upon pregnant women, in all of which the pregnancy had gone on to term without interruption.

Periodicity in the Physiological Functions of Women.—DR. DIMITRI V. OTT, of St. Petersburg, presented a communication on this subject in which he showed, as a result of numerous observations made by him on women and girls of different ages, that, in addition to the nervous phenomena observed in women at the menstrual period, there is a series of variations of normal functions appearing periodically in a typical form. The curves of temperature, muscular strength, blood-pressure, respiration, and nervous irritability all attained their maximum shortly before menstruation, sinking again to the normal after the menstrual function had begun.

Extirpation of the Uterus.—DR. JOHN WILLIAMS, of London, opened the discussion on this subject with a

paper on "Vaginal Hysterectomy in Cancer." In case of cancer of the fundus the indications for operation depend upon the size of the uterus and its mobility, the presence of adhesions, and the extension of the disease to neighboring or distant parts. In the case of cancer of the cervix and of the portio vaginalis the propriety of operation depends upon the pathological variety of the neoplasm and upon the physical condition of the patient. Before attempting an operation we must take account of the duration of the disease, its primitive seat, and its mode of extension. In cases in which supra-vaginal amputation has been performed we must be guided in our further course by the seat of the recurrence and its mode of development. In cases of cancer of the body coinciding with that of the cervix we must consider the origin of the disease, whether it is by simple extension or by metastasis, or whether there has been a simultaneous development at both points. It is impossible to determine from the statistics at present available whether or not the results after total extirpation are better than those after supra-vaginal amputation of the cervix, but the author regarded the latter operation as the most justifiable in the majority of cases of cervical disease.

Dr. Schauta, of Prague, thought that partial operations were not justifiable in those cases in which a more radical procedure was possible. He had come to this opinion as a result of numerous observations showing disease to exist in the body of the uterus when it had occurred primarily in the cervix. The extension of the neoplasm in depth constitutes one of the most important points in operative diagnosis, for when the disease has progressed so far that there is no hope of the patient being restored to health, an operation should not be undertaken. The mere fact of extension of the disease to the rectum or bladder is not in itself a contra-indication to operation, the sole element to be considered is the degree of involvement of these organs. In addition to malignant tumors, prolapse, fibroma, or recurring glandular metritis may in certain cases furnish an indication for operation.

Dr. Pozzi, of Paris, favored total extirpation of the uterus as soon as it had been determined that cancer of the cervix existed. He did not regard vaginal hysterectomy as a graver operation than amputation of the cervix, and thought it ought to be preferred, since it was impossible to determine clinically that the disease was limited strictly to the cervix. The operation should, however, be reserved for those cases in which the new-growth was limited to the uterus itself, for when other organs were involved the operation became so much the more grave and the chances of a recurrence were greatly increased. As to the technique of the operation, he strongly deprecated forced retroflection, because of the increased danger of infecting the peritoneum. Progressive ligature of the tissues is preferable to the forcipressure advocated by Péan, as it obviates the danger of wounding the bladder, urethra, or rectum.

Dr. Olshausen, of Berlin, favored total extirpation in suitable cases, but the difficulty was that a diagnosis was usually made at a time when it was too late to gain much by the operation. He agreed with Pozzi in deprecating forcipressure.

Dr. Martin, of Berlin, was in favor of total extirpation in cancer and other incapacitating affections of the uterus. He did not lay much stress upon the method of operation, the main point being the complete removal of the organ.

Dr. Péan, of Paris, favored the operation in all suitable cases. He advocated strongly the practice of forcipressure, saying that he had had an extended experience with this procedure and that it had always given very satisfactory results in his hands.

The Causes of Rotation of the Fœtal Head.—Dr. Schatz, of Rostock, read a paper on this subject. After reviewing the theories advanced by Nägele, Schröder, and others, he presented a statement of his own views, which were, in brief, as follows: The typical obstetrical pelvis was to be regarded as a canal of circular form, so bent that its entrance and exit planes were at right angles to each other. The deviation which race formation caused in this form was compensated for by the capacity of configuration of the fœtal head. Mechanically, the head was to be regarded as oval. The longitudinal axis of an oval body pushed forward in a narrow canal was synagonal with the axis of the canal. Now, how did the rotation take place? This followed from the eccentric insertion of the vertebral column in the head. This eccentric fastening held the head back, and the rotation of the head took place in consequence. So long as the uterus was shorter than the fœtus lying pressed together in it, the form-restoring power of the uterus acted as a forward-driving force.

Dr. Zweifel, of Leipsic, followed with a paper on "The Mechanism of Delivery," in which he gave his theory on the cause of rotation of the fœtal head. Dr. Pestalozza, of Pavia, exhibited an instrument for recording the fœtal pulse. Other papers were read by Dr. Küstner, of Dorpat, on "The Formation of Amniotic Bands;" by Dr. Neugebauer, of Warsaw, on "The Treatment of Chronic Inversion of the Uterus by Hydrostatic Pressure;" by Dr. Skutsch, of Jena, on "Measurements of the Pelvis;" by Dr. J. Stuart Nairne, of Glasgow, on "Causes of Incontinence of Urine in Women, and its Surgical Treatment;" and by Dr. J. Chalmers-Cameron, of Montreal, on "The Influence of Leucæmia on Pregnancy and Labor."

Third Day, Wednesday, August 6th.

Treatment of Cystitis in Women.—Dr. More Madden, of Dublin, read a paper in which he described a method of treatment of this distressing condition that had been very successful in his hands. The measures most commonly employed in such cases were merely palliative, and may relieve, but *per se* can never cure well-established cystitis in women. He was not aware of any method by which that could be accomplished save by giving the bladder absolute physiological rest. For this purpose Dr. Emmet's operation—*i.e.*, the establishment of an artificial vesico-vaginal fistula—may be successfully employed in some instances, but the practical objections to it were so great and obvious that for several years past he had abandoned this procedure in favor of another which was found more generally effectual, and quite free from the disadvantages of the operation referred to. His plan consisted, first, in the full dilatation of the urethral

Dr. Grainger Stewart, of Edinburgh, spoke particularly of the influence of climate upon sufferers from chronic renal troubles. He had seen two cases of albuminuria caused by residence in a malarious district. Patients should be very careful also in regard to clothing, being always warmly clad. In regard to diet, the speaker agreed with Dr. Lépine. He divided the different kinds of diet which he ordinarily prescribed into four classes, as follows:

Diet.	Albumin. Ounces.	Carbohydrates. Ounces.	Fats. Ounces.
Ordinary	4.665	10.65	3.32

Drainage after Laparotomy.—Dr. E. W. Cushing, of Boston, read a paper on this subject, in which he recommended the use of drainage-tubes in the following cases: 1. When any condition was present which would lead to the belief that there would be for some time an oozing of bloody fluid, as, for example, when there had been a separation of extensive adhesions, when there was a thick pedicle, or when long incisions in the peritoneum necessitated the employment of many sutures. 2. When there had been an escape of much blood, or of urine, fæces, or the contents of a cystic tumor into the abdominal cavity. 3. When there had been a wound of the intestines or bladder, or when either of these organs was in such a condition as to suggest that subsequent perforation might occur. 4. When there was present an unyielding mass

of exudation substance preventing sinking in of the surrounding tissues, and thus favoring the accumulation of fluid. 5. When, for any reason, it was found necessary to terminate the operation speedily before the water could be all drained away from the peritoneal cavity. The speaker saw no special contra-indications to the employment of drainage after abdominal section.

Dr. Saenger, of Leipsic, followed with a paper on the same subject, in which he took the Continental view in favor of antisepsis and against the common employment of drainage in these cases.

Dr. Boldt, of New York, took a middle ground, believing that the measure was employed with too great frequency in America and England, but not often enough in Germany. He advocated drainage in cases in which pus had entered the abdominal cavity, as in difficult pyosalpinx operations, provided that the peritoneal cavity could not be satisfactorily washed out. He preferred a double-current drainage-tube.

Dr. G. M. Edebohls, of New York, exhibited a self-retaining vaginal speculum for use during examinations and operations in the dorsal position, and also an improved antiseptic lock for surgical instruments. He further showed a model of a table for use in antiseptic laparotomy operations.

Treatment of Obstructive Dysmenorrhœa.—Dr. T. More Madden, of Dublin, read a short paper on this subject, and exhibited an instrument which he had devised for the rapid dilatation of the cervical canal. This instrument differed from other dilators in several respects, and especially in one which the author considered most important, viz., in producing expansion of the canal from within outward; in other words, in imitating the natural process of expansion from the uterine cavity downward to the os uteri; whereas most other dilators, such as Hegar's, etc., act in the opposite direction. In his own hands the utility of this instrument, the expansion effected by which may be measured by the affixed index, had been fully tested in a very large number of cases of sterility and dysmenorrhœa in hospital and private practice. The dilator, which does not occupy more room than the ordinary sound when introduced, may also be used, Dr. Madden said, with advantage for the dilatation of the female urethra in many cases in which this procedure is indicated.

Peritonitis from Rupture of an Ovarian Hæmatoma.—Dr. H. J. Boldt, of New York, reported a case of this accident in which recovery followed the performance of abdominal section. The patient was thirty-one years old, [illegible] preferred because of the [illegible] afforded. The presence of students need not be feared if only the antisepsis be carefully preserved.

Dr. Stadfeldt, of Copenhagen, said the introduction of antisepsis in midwifery had made it possible to turn the large lying-in institutions to account for teaching purposes without prejudice to the patients. Antisepsis was of great advantage to the new-born as well as to the women. In private practice midwives should keep their clothes, persons, and instruments thoroughly aseptic. They should not attend the woman after her confinement if she developed any puerperal disease. They should be [illegible] something about the patient was [illegible] worse, so that he considered laparotomy to be the only possible chance. This was done while the woman had a temperature of 104° F. and a small, rapid pulse of 140. Recovery was prompt.

The interesting feature of the case was the almost fatal result from a hemorrhage from a spontaneous rupture of a hæmatoma not larger than a cherry. Dr. Boldt showed the specimens and entered into the etiology of ovarian hæmatoma, which he considered to be always preceded by an angiomatous condition. It is impossible to make the diagnosis of the condition, although it may occasionally be suspected from the history and physical condition of the patient.

Extra-uterine Pregnancy.—Dr. Boileux, of Paris, reported a case of extra-uterine pregnancy terminating in spontaneous cure at the third month. The patient was thirty-four years of age and had been married thirteen years, having had one child at term and two miscarriages. She menstruated last early in March, and in April began to have an abundant bloody discharge, which continued, in spite of treatment, for about three weeks, rendering the patient very weak and exsanguious. The woman complained of a constant pain in the right leg. On examination the os was felt to be soft and patulous. The uterus was anteflexed, hypertrophied, and very immovable. To the right of the uterus and a little posterior was a small tumor, which to the touch resembled the bulging fœtal membranes during labor at term. A threatened abortion was suspected and the patient was put upon opiates. She remained in about the same condition for several weeks. Finally, toward the end of May, there was a very severe attack of pain in the right thigh, in Scarpa's space, and also pains resembling those of labor. Following this attack there was an expulsion per vaginam of a membrane which microscopic examination showed to be decidual. At the end of June normal menstruation returned. Mounted specimens of the expelled membrane were shown under the microscope.

Fourth Day, Thursday, August 7th.

Induction of Premature Labor.—Dr. Theophilus Parvin, of Philadelphia, opened the discussion on this topic. He had tabulated about one thousand cases of induced premature labor, showing the conditions which had necessitated it. Among these were albuminuria, diseases of the heart or lungs, uncontrollable vomiting, etc. The most frequent indication for the induction of labor was, however, pelvic deformity. It was difficult to decide as to the relative merits of this operation and of Cæsarean section in cases of deformed pelvis, and no hard and fast rule could be laid down, each case needing to be judged by itself, of no slight importance in the decision being the experience and skill of the obstetrician called upon to manage the case. In cases of nephritis or uncontrollable vomiting it was often a very difficult question to determine whether to induce labor or not. In many such cases the operation was of benefit, while in others it did a great deal of harm.

Dr. Macan, of Dublin, said that this question had changed somewhat since the introduction of antiseptics. In former years it was dangerous to the mother as well as to the child, but now it was, as a rule, no worse for the woman than an ordinary case of labor. If the labor was allowed to go on to term in cases of contracted pelvis, there would ordinarily be the question of perforation or of Cæsarean section. The latter operation was formerly very fatal to both mother and child, but now its dangers had been greatly diminished, and its performance often resulted in saving both mother and child. The life of the child should not be sacrificed lightly, yet it was the woman herself who should decide whether she would run any extra risks in hope of saving the unborn infant. Even induction of premature labor was not perfectly safe, for it was not always possible in tedious cases to insure perfect asepsis. In regard to the technique of the operation, he held that it was better to use no instruments or tents for dilating the os, the finger being in all cases far more safe, and in every way preferable.

Dr. Calderini, of Parma, read a paper on the same subject, considering chiefly the indications for and against the procedure furnished by pelvic measurements. In the interests of the child, the induction of premature labor should not be entertained when the conjugate, in a rachitic pelvis, was under 75 mm. In non-rachitic pelves, induced labor, under antiseptic precautions, would be allowable up to 85 mm., or even a little more. By means of special precautions it might be possible to materially reduce the mortality of children born alive after induced labor. The employment of antisepsis had greatly diminished the risks of the operation to the woman. The

best way of inducing labor in cases of contracted pelves was the use of hot douches through a speculum, and the introduction of a bougie as far as the fundus. When labor was induced for visceral disease it was often necessary to add to the above puncture of the membranes.

The speaker presented the following table showing the results obtained by the various procedures employed in Italy in cases of retracted pelvis:

Operation.	Number of cases.	Mortality of the mother.		Mortality of the child.	
			Per cent.		Per cent.
Version	65	3	4.30	21	32.30
Forceps at the superior strait	193	14	7.25	45	23.31
Perforation	144	20	13.88	144	100.00
Cæsarean section (Porro)	59	19	32.70	9	15.51
" " (Sänger)	23	10	43.47	2	8.69
Induced premature labor	305	14	4.59	82	26.88
Symphysiotomy	23	3	13.04	5	21.74

In the interests of the child preference should be given to Cæsarean section, but the risk to the mother was still great, and, in practicable cases, induced labor should be preferred.

Dr. Dohrn, of Königsberg, agreed with the previous speaker as to the indications furnished by pelvic measurements. He thought the value of induced premature labor was in no way lessened by the better results that had been recently obtained by craniotomy and Cæsarean section, and induced labor would still remain an operation without a rival in a large proportion of cases.

SECTION ON INTERNAL MEDICINE.

First Day, Monday, August 4th.

The first session was held on Monday afternoon, and was devoted to the organization of the Section. The following honorary presidents were chosen to represent the different countries: England, Sir John Banks and Drs. Grainger Stewart and Pavy; France, Drs. Bouchard and Lépine; Italy, Drs. Bacelli and Cantani; Austria, Drs. Przibram and Schrötter; Russia, Drs. Kernig and Levasheff; Holland, Drs. Stokvis and Rosenstein; United States, Drs. Jacobi and Osler; Belgium, Dr. Crocq; Norway, Dr. Klaus Hansen; Sweden, Dr. Warfringe; Denmark, Dr. Trier; Switzerland, Dr. d'Espine; and Mexico, Dr. Carmona y Valle.

President's Address.—Professor Leyden, President of the Committee on Organization, then delivered a short address, extending a cordial welcome to the members of the Section. He spoke first of the potent influence of an international gathering of this kind in favor of peace between nations, and of a higher civilization which such peace must bring with it. Then he referred to the fact that, although there was now a strong tendency to specialization in medicine, yet there was all the more need of a central guiding hand, and this Section was that guiding hand, the mother of all the specialties, and the one who alone could gather together the results of the labors of all her children, and use them to the best advantage of all. He reminded his hearers that the object of medicine was not only to study disease by itself as a matter for scientific investigation, but also, and chiefly, to discover the means of relieving suffering, and curing the bodily ills of mankind. After drawing attention to the growing tendency to the employment of dietetic and hygienic measures in the treatment of disease, he closed his remarks with a few words of hearty welcome, expressing the hope that much good would result from the labors of the Section, which were now to begin.

Second Day, Tuesday, August 5th.

Treatment of Chronic Bright's Disease.—Dr. Lépine, of Lyons, opened the discussion on this subject. The danger of a chronic nephritis being the insufficiency of the renal secretion, the principal indication is to overcome this insufficiency. But in favoring increased secretion of urine care must be taken not to put too much work on the already diseased kidneys. On the other hand, it is necessary to keep up the nutrition. We must nourish the patient and stimulate the secretion of urine without irritating the kidneys—two indications which seem to be opposed, but which can yet both be satisfied. In the matter of food, we must diminish the amount of albuminoids relatively to the hydrocarbons and fat, since the waste products of the latter are not excreted by the kidneys. Although it is theoretically somewhat too rich in albuminoids, nevertheless milk is the best food for the patient with kidney disease. It contains no waste materials, and all the nitrogenous substances are utilized in the economy; it is rich in fats, contains nothing which can irritate the renal epithelium, and finally is diuretic. But it is usually impossible to keep the patient on a pure milk diet, and it will be found necessary to supplement it with digestible vegetables, bread, farinaceous foods, etc. It is, above all, important to attend to the condition of the digestive functions, since when the digestion is poor many toxic principles are formed which will serve only to irritate the kidneys. Although albuminuria is a symptom of transudation and apparently independent of the amount of secretion, yet we do not know what the relation between the two is, and it is therefore prudent to restrict the patient in the use of eggs, and sometimes of fish, if these appear to increase the amount of albumin excreted. To favor diuresis we may have recourse to slightly alkaline mineral waters, which sometimes are sufficient for the purpose. But when the diminished secretion is accompanied by signs of cardiac weakness we must employ heart stimulants. In the first rank of these remedies the author placed crystallized digitalin. This should, however, be given with great caution, and only every other day or even at longer intervals, in order to insure its complete elimination. Caffeine, in doses of at least fifteen grains hypodermically, was sometimes of service. Strophanthus should not be given, since it had a tendency to irritate the kidneys. Iodide of potassium, which is a diuretic, is chiefly indicated when there is arterio-sclerosis. The author was opposed to the employment of vapor baths in cases of dropsy, fearing uræmia, but he always advised rest in bed, by means of which an even temperature of the skin could be maintained. Of course it was necessary to avoid all exposure to cold and wet. Uræmia was what every patient with chronic Bright's disease had most to fear.

Dr. Grainger Stewart, of Edinburgh, spoke particularly of the influence of climate upon sufferers from chronic renal troubles. He had seen two cases of albuminuria caused by residence in a malarious district. Patients should be very careful also in regard to clothing, being always warmly clad. In regard to diet, the speaker agreed with Dr. Lépine. He divided the different kinds of diet which he ordinarily prescribed into four classes, as follows:

Diet.	Albumin. Ounces.	Carbohydrates. Ounces.	Fats. Ounces.
1. Ordinary	4.665	10.65	3.32
2. Large	6.86	13.07	4.6
3. Milk	3.2	3.84	2.96
4. Low	2.494	16.06	2.202

He usually combined the milk with a low diet, obtaining better results thereby, as a rule, than with either separately. The first two diets on the list were only exceptionally admissible in cases of Bright's disease, since they would cause an increase in the amount of urea and albumin excreted. By the addition of lime-water or selters, the milk could be made more palatable and at the same time more digestible. He knew of no remedy for the disease. In cases of uræmia he recommended pilocarpine and hot-air baths, and when the pulse was very tense nitro-glycerine was of service.

Dr. Rosenstein, of Leyden, thought the greatest ad-

vance made in the treatment of this class of diseases was in the direction of improved hygiene and dietetic therapy. No medicines were of any benefit, except in the treatment of the complications arising during the progress of the malady. Even in the matter of diuretics in dropsy, it should be remembered that simple rest in bed was often sufficient to cause the disappearance of the fluid. The speaker protested against the use of calomel as a diuretic, for this drug was excreted with difficulty by the diseased kidneys, and might readily produce ptyalism or even gangrene of the mouth. He was not very partial to the indiscriminate use of milk, which often excited a mild form of gastritis, and also was so strong a diuretic that it frequently caused patients to rise at night, thereby disturbing the rest which was so necessary for them.

Dr. Senator, of Berlin, agreed with the previous speakers as to the inefficacy of drugs in the treatment of chronic nephritis. The albumin often varied greatly in amount from day to day when no drugs were given, and it thus happened that certain remedies had acquired a reputation which they did not deserve, their exhibition having chanced to precede one of the accidental falls in the amount of albumin. In certain varieties of nephritis dependent upon arterio-sclerosis, however, iodide of potassium was of real service. In patients suffering from arterio-sclerosis this drug should be given as soon as albumin appears in the urine.

Dr. Aufrecht, of Magdeburg, said that he had repeatedly tried the use of iodide of potassium in such cases, and had never seen the slightest benefit result from its employment.

Treatment of Phthisis in Institutions.—Dr. Hermann Weber, of London, opened the discussion on this subject. After referring to the remedies usually employed in this disease, and which he regarded as useful only in the treatment of symptoms and as tonics, he said that it was not too much to hope that the time was not far off when some specific remedy would be found which would be capable of destroying the bacillus without working injury to the human organism. The main reliance in the treatment of consumption is to be placed upon a dietetic and hygienic regulation of the patient's life. Climate was not to be overlooked in the management of these cases, but it should be selected on correct principles. That climate was the best which would permit of out-door life, as a result of which the appetite was increased, the general health improved, and the respiratory and circulatory organs strengthened. Mountain climates possessed some advantages, but the treatment of phthisis could be carried out in any place where there was pure air and plenty of it day and night, where good food could be obtained, and where there was opportunity for the patients to take all the necessary exercise. The main point in the treatment of this, as well as of many other chronic disorders, was to maintain the general strength of the patient and to favor the proper performance of all his functions. This was to be attained only by a properly directed constitutional therapy. A patient with tuberculosis ought to be under the constant supervision of a competent physician, whose duty it should be to regulate every detail as to food, clothing, exercise, etc., watching the varying conditions of health of his charge, and adapting his daily prescriptions in these matters to the requirements of the case. It was here that the great advantage to a consumptive of residence in an institution lay, and to prove that such a view was not theoretical merely, the speaker instanced the benefits derived by patients in sanatoria such as Ventnor, in England, and the cottages at Saranac Lake, in the Adirondacks. The author dwelt upon the benefits that would accrue not only to the patients themselves, but also to the community, if a number of such institutions could be established for the reception of the poor. The results of hospital care would be not only the relief of much human suffering, but also the restoration of numbers of invalids to health, rendering them useful to their families and to the community as well.

Dr. Leyden, of Berlin, said that he had listened with pleasure to Dr. Weber's address, and believed that it would do great good in giving an impulse to the movement, already noticeable in Germany, toward the establishment of sanatoria for the reception of the poor suffering from pulmonary tuberculosis. Undoubtedly the best treatment of consumptives could be carried out only in institutions of this kind, and even if the hopes of Koch as to the ultimate curability of tuberculosis should be fully realized, such sanatoria would still be necessary, at least for a long time to come.

Dr. Detweiler, of Falkenstein, was rejoiced to hear such plain words in favor of the hospital treatment of phthisis, and it might be said that the controversy concerning the utility of institutions of this sort was now closed, for the good results following their establishment were too evident to bear contradiction.

Dr. Paul Kretzschmar, of Brooklyn, described the Adirondack sanatorium and other similar institutions in the United States.

Dr. Cantani, of Naples, said that he had long noticed the fact that rabbits inoculated with tuberculosis would resist the disease for a considerable time if they were well fed and placed where they could get plenty of fresh air and sunlight. He had also noticed that carnivorous animals resisted much better the action of the tuberculous virus than the herbivora. In the food of carnivora sodium salts predominate, while in that of herbivora there are more potassium compounds. This furnished a hint of some value in the therapeutics of consumption. In Italy there had for more than a century been institutions for the reception of consumptives, but these were rather places of refuge than hospitals. There had always been a popular belief in the contagiousness of phthisis, and for this reason the unfortunate without a home of his own could seldom find a place, and it therefore became necessary to establish institutions to harbor such patients. The existing refuges were, however, unsanitary to the last degree, and were little more than places to die in.

Dr. Trier, of Copenhagen, spoke of the hospitals for consumptives in Denmark.

Drs. Fuerbringer, of Berlin, Hansen, of Bergen, Cutter, of New York, Philip, of Edinburgh, Rocha, of Coimbra, and Schroetter, of Vienna, also took part in the discussion.

Intracranial Pressure.—Dr. Adamkiewicz, of Cracow, reported some experiments which he had made, which overthrew, he thought, the previously generally accepted mechanical theory of brain pressure. As soon as the intracranial pressure becomes greater than that in the veins of the skull, the fluid flows into the latter. If these are unable to carry off all the fluid, intravenous pressure rises, stasis ensues, and œdema of the brain is produced. It is this œdema which gives rise to the pressure symptoms, and the latter are therefore not the direct result of the increased amount of cerebro-spinal fluid.

Drs. Ebstein and Nicolaier, of Göttingen, presented some urinary calculi formed of oxamid which had been obtained as a result of feeding this substance to dogs.

Operative Treatment of Serous Pleurisy.—Dr. Levasheff, of Kazan, recommended the withdrawal of a certain amount of the intrapleural exudate, and replacing it at once with an equal quantity of a solution of chloride of sodium. After this operation had been repeated from two to six times the pleural cavity would contain practically nothing but an indifferent salt solution which would be rapidly absorbed.

Dr. Fuerbringer, of Berlin, thought that the last speaker's experience only showed how much an inflamed pleura could stand in the way of trauma. He believed a simple puncture was all-sufficient in such cases, and it was needless to complicate it with injections of salt solutions or of any other fluid.

Treatment of Nocturnal Enuresis in Children.—Dr. Van Tienhoven, of the Hague, read a paper on this subject, in which he held that incontinence of urine in

children depends upon an insufficiency of the sphincter vesicæ muscle, which allows the urine to enter the upper portion of the urethra, whence it is expelled by a reflex action of the detrusor urinæ. The enuresis occurs usually during the first two hours of sleep, before it is ordinarily possible for enough urine to be secreted to distend the bladder. To prevent the incontinence the author recommended that the little patients sleep upon a bed raised at the foot, so that the urine should flow away from the neck of the bladder, thus taking away the source of the irritation. In fourteen children whom he had so treated in hospital practice a cure was speedily obtained without the use of any drugs, the only precautions being to see that the patient emptied his bladder thoroughly before retiring, and that he took no fluids for a time before going to sleep.

Pathology of the Abdominal Sympathetic.—Dr. Talma, of Utrecht, presented a communication on this subject, in which he traced the part taken by the sympathetic in the production of various diseases of the stomach and intestines, especially of gastric ulcer.

Bacelli's Sign.—Dr. Gaetano Rummo, of Pisa, reported a number of cases which he had examined to test the reliability of Bacelli's sign in the diagnosis of intra-pleural exudations. This sign consists in the fact that if, in case of an intra-pleural effusion, the whispering voice is heard by the ear resting against the abdominal wall, the effusion is certainly serous. He had satisfied himself that this sign was a reliable one. The conductivity of the thorax for the whispering voice was influenced solely by the number of corpuscular elements contained in the exudate, and not by intra-pleural pressure, the amount of fluid, or the condition of the pleural surface.

Dr. Bacelli, of Rome, expressed his satisfaction to learn that further tests had demonstrated the reliability of this diagnostic sign, discovered by him in 1875. Some confusion had arisen from this symptom being confounded with the sign called by Guéneau du Mussy "pectoriloquie aphone." The conductivity of pleuritic effusions for the whispering voice has nothing to do with true aphonic pectoriloquy.

BRITISH MEDICAL ASSOCIATION.

Fifty-eighth Annual Meeting, held at Birmingham, England, July 29, 30, 31, and August 1, 1890.

(From our Special Correspondent.)

(Continued from page 249.)

SECTION IN MEDICINE AND THERAPEUTICS.

Second Day, Thursday, July 31st.

Dr. Rickards, of Birmingham, in the Chair.

Localization, as an Aid to Diagnosis and Treatment, of some Forms of Headache.—Dr. Hewetson, of Birmingham, read a paper on this subject. The author mentioned that for the past fifteen years he had been working upon the subject of the localization of head pains. In 1884 he had noticed that astigmatism was a frequent cause of localized headache, and similarly he had begun to observe that each cause of pain seemed to have its locality in the cranium. Megrims, for instance, was often curable by getting the patient to make use of converging lenses. It was his observation that in numbers of cases where headache existed there was very little defect of vision present. For instance, a clergyman, who had passed with high honors in Oxford, recently consulted him for headache, and he found that this gentleman was highly hypermetropic. He had suffered much from headache and had been treated by all sorts of drugs. A suitable pair of spectacles, continually worn, cured the patient. The brother of this gentleman also suffered from extreme hypermetropia and was very neurotic in character. It was, the author maintained, very important to recognize defective vision as a cause of headache in childhood, for, if this were not done, the patient might suffer terribly in after-life from all kinds of ill-health. Some patients with defective vision suffered much from insomnia. In other cases headache was due to diseases of the teeth, even when the patient suffered in no way from toothache. The regions where pain was most notable in astigmatism were the frontal region, the top of the head, and the temporal fossa. This did not resemble the vertical headache noticed in anæmia. There was nearly constant pain, accompanied by sick headache. The spot in the temporal fossa was just at the outer part of the brow. In the case of decayed upper molars in a patient with two quiescent carious upper molars, the pain was localized in the frontal region. Decayed lower molars exhibited similar painful spots at the extremity of the eyebrow. When there were blows on the cornea with pieces of coal or iron the head pain was localized in the back of the neck. It was curious that myopia did not give much pain in the head. Hypermetropia caused far more. The spasm of a microscopical eye ("accommodation spasm") caused pain in the back of the head. In this case there was temporary astigmatism. It was, then, the astigmatic eye on the one hand and the hypermetropic eye on the other which were apt to be accompanied by constant headache. In one case of epilepsy and dizziness he had quite cured his patient by means of suitable lenses.

Dr. Drummond, of Newcastle, had for some time recognized that a large number of headaches were due to defects in vision, but the results of treatment based upon this experience had not been quite so satisfactory as he had expected. Perhaps the reason of this was that the spectacles had not been worn continuously by the patients, and he supposed that they should be worn constantly. Myopia did not produce headache so frequently as astigmatism did, or as hypermetropia. The headache of influenza was noticeable. It was all over the head and the scalp was tender. Chloride ammonium was a wonderful remedy in these cases. There was one point which must be mentioned and that was that we must recognize a neurotic condition in almost all headaches. For instance, patients with carious teeth might be entirely free from such headaches in some instances; whereas, in others, caries would cause great and terrible suffering.

Dr. Tyson, of Folkestone, said that he had seen many cases of frontal headache associated with myopia and with astigmatism. A member said that, as symptoms of a neurotic condition, it was well to examine the carotid arteries and their pulsation. In cases of neurasthenia there was a tuberosity of the carotid vessels, and the vessels were too round and had certain other peculiarities in such patients. There were also certain muscular symptoms of neurasthenia. After a fagging night a person might be called "seedy." This referred to a dark coloration around the orbit and to slight dropsical effusion under the sclerotic. It would be interesting he said, if oculists would inform the profession how many of their patients with hypermetropia and astigmatism suffered from headache. He said this because there was probably some other factor in the production of the headache besides the eye trouble, just as in the case of caries of the teeth, which caused so much agony in certain persons and so little pain in others, sometimes all the teeth might be carious and no pain exist.

Dr. Jones, of Southampton, would like to hear what effect the condition of the muscles of the eyeball had upon the production of headache. In his own experience myopic astigmatism was often accompanied by the severest form of headache. The continued use of glasses was of the greatest service in such cases. One difficulty he had found in getting such patients to wear glasses habitually was, that the patient did not see well when walking about, and was therefore unwilling to wear them until he gradually became accustomed to them, when he no longer felt afraid of them.

Dr. Hewetson, in reply, pointed to some other diagrams, which referred to frontal pain of nasal stenosis. This frontal pain was often accompanied by pain along

the nose. This condition of the nostrils was often of the gravest importance to the health of children. Such patients were the so-called "mouth breathers," who were incapable of breathing for a longer period than about twenty seconds through the nostrils. He referred to Dr. Lauder Brunton's localization of headache as connected with the teeth and eyes. That author localized the first class of pains in the temporal region and the latter class in the occipital region. He repeated what he had said at Glasgow, that the slight cases were by far the most troublesome, and caused the most mischief, because they were unrecognized. There were also the cases which were fitted with improper glasses. For instance, he had not unfrequently seen patients who, being myopic, had been using plus glasses prescribed for them by vendors of glasses. General neuroses were, far oftener than was supposed, due to optical defects. Myopic astigmatism was certainly a frequent cause of headache and vertigo and even might go so far as to cause attacks of "petit mal."

Typhoid Fever in Hindostan. — Dr. Hamilton, Brigade Major, of Lucknow, read a paper on this subject, in which he pointed out how important it was for all persons likely to practise medicine in tropical countries to be familiar with the symptoms of typhoid fever. Some persons thought that this disease had been only met with in very recent years in Hindostan, but he, Dr. Hamilton, thought that there was abundant evidence in disproof of this opinion. On the other hand, the mortality from this fever now far exceeded in Hindostan that of all other diseases even cholera. Relapsing fever had become very much less a cause of death since the use of quinine, and hence typhoid fever had become the most dreaded of all fevers in the East. To give an idea of its prevalence he would state that while in the United Kingdom last year there had been among the 101,000 troops stationed in these islands only 34 deaths from typhoid fever, nearly 1 in 33 of the troops in Lucknow had been fatally attacked by the disease, or 89 in 2,700 had died of the disease in twelve months. Such facts showed the extreme importance of the study and prevention of typhoid fever in India. The mere economical loss to the Government of India was very large from this disease. The patient was three months ill, and was unfit for duty for six months. Fifty deaths cost the Government no less than £10,000, and in four years no less than £27,000.

With regard to the causation of typhoid in Hindostan, there were, firstly, youth and the recent arrival of the soldiers to be mentioned. In Lucknow, sixty five per cent. of the troops had resided less than two years in the country. Formerly, indeed, men were sent to Hindostan at the age of eighteen, and were there for twenty years. Heat acted in two ways on such persons. Firstly, by weakening the patient, as the temperature was often as high as 120° F. in the shade. Secondly, by causing rapid putrefaction. Locating troops in cooler parts of the peninsula was an excellent remedy. Over-stimulating diet was often a predisposing cause, as it was often digested with difficulty. Farinaceous diet was probably more easily assimilated than the tough steaks, washed down by beer which the troops were accustomed to. If the British troops were less conservative in their diet, it would doubtless be of service to them in Hindostan; but this was a matter in which little was to be hoped for in the way of change. Typhoid fever should be rare among the troops in India, if only they could secure the cleanliness around the barracks which prevailed within their precincts. With the dry earth system of closets, fecal fermentation as a cause within the barracks was out of the question, and the water supply also was most carefully seen to and was excellent. But, outside of the barracks, dirt reigned supreme. There was, indeed, no sanitation whatever in Hindostan, and the English soldier lived in oases of cleanliness in the midst of deserts of filth. Thus the young soldier was exposed to innumerable dangers. In the first place, the milk supply was horribly unclean. Even when the cows were within the precincts of the hospital, the native milkers were sure to mingle filthy water with it, and cause all sorts of dangerous epidemics in this way. The food bought in the bazaars was filthy, as were all the surroundings of these places, and the soldiers could not be prevented from frequenting them, and drinking lemonade and other drinks made with the most impure water. Government ought, of course, to have dairies of its own; but it was difficult to get such changes as this amounted to. The native cows were fed on all sorts of filth. Then, again, the plunge-baths used by the troops were emptied only once a month, and became sources of typhoid fever from the water into which the excretions of typhoid patients were sometimes poured. With respect to the symptoms of typhoid fever in Hindostan, they were almost identical with those familiarly seen in practice in England. Constipation, however, more frequently accompanied the fever than was the case in this country. The treatment was the same as it was at home; no special drug was used. In conclusion, Dr. Hamilton said that the subject of typhoid fever in Hindostan might now be considered of national importance, since so many young men, from the wealthiest to the poorest classes, left home to inhabit that country.

Entric Fever Increasing in India.—Dr. Rickards, of Birmingham, said that the Section was indebted to Dr. Hamilton for his important communication, which had been full of novel truths to all who had listened to it. It seemed that, while the deaths from other fevers had gone on diminishing in India, those from enteric fever had gone on increasing in frequency. With regard to the causes assigned for this frequency, Dr. Hamilton had adverted to youth and recent arrival in the country as causes. Of course, the generally received opinion on this matter, which he shared in, was that there could be no such fever without its germ and that in addition to this germ there was needed a suitable nidus for it to flourish in. It was now generally admitted that no kind of fermentation would cause typhoid fever unless the germ were present also. When the young recruits arrived in Hindostan doubtless the state of their age and health rendered them very susceptible to the influence of the typhoid poison. Dr. Hamilton's description of the way in which milk was supplied to the troops was most important, and well explained the frequency of this disease, which was so often spread by impure water supplies. Water was the great carrier of typhoid contagion, and milk, because it was so often adulterated by such dangerous water as had been spoken of by Dr. Hamilton.

Dr. Drysdale said that few topics could be more important to the British in Hindostan, and also to the natives of that immensely populous peninsula than this question of the increase of typhoid fever. The chief point in this matter was to become convinced that typhoid fever could never originate *de novo*, however filthy a population might be, unless some person with the disease came into the country. This had been clearly known to the medical professors ever since the work of Dr. Bancroft in 1812, who had shown that no amount of putrefaction or filth was capable of producing a fever, unless the germs of such fever were present. He pointed to the slave ships, which were filthy to the last degree, but which were never attacked by fevers, and to the putrefaction which was found in the underground huts of the inhabitants of Kamschatka, where, however, such diseases were unknown. He would like to know whether there was any history that typhoid fever had existed in Hindostan before the French and English went thither. He should presume that this was probably not the case, for in new colonies, such as Australia and New Zealand, the disease had often been clearly introduced by colonists. There was no use in going on with any discussion about predisposing causes until this point was fairly settled: and he considered that those who spoke of the *de novo* production of typhoid fever, small-pox, or leprosy were, whether in or out of the profession, most dangerous to the cause of hygiene and longevity. Heat, of course, might predispose to

fever of any kind, but no amount of heat, even 120° F. in the shade, would produce a single case of typhoid fever in one thousand years unless some patient suffering from the disease infected the water, air, or otherwise poisoned the system of his neighbors. He could not too strongly emphasize this opinion, because he was certain that if the authorities in Hindostan would act as if typhoid fever were a contagious disease they might free both the British and the natives from what was, he believed, a disease which had originated in Europe and been conveyed to Hindostan. On the contrary, if they went on debating the origin of this fever in filth they would lose time and the disease would spread as it had done throughout the whole of that most abominably filthy Eastern country. Dr. Hamilton had alluded to the high death-rate in the barracks in Dublin; and those who had visited that city some years ago with the British Medical Association would remember with horror the condition of the Liffey which ran close to their dismal barracks, and which was a disgrace to the civilization of the British islands.

Climatic Fever.—Sir William Moore, of Hindostan, said that if the old medical Indian officers were referred to, it would be seen that the fevers in that country were the same long ago as they were at the present day. Hewitt, in 1850, however, was the first writer on Hindostan to describe typhoid fever clearly. What was now styled enteric fever had, however, existed long before that writer. If enteric fever was considered a specific fever it was very difficult to account for the fact that in Hindostan it was not caused in the same way that it was in this country. The natives who removed the night-soil were not affected by typhoid fever. Kurrachee was a remarkably salubrious place, and yet there was much typhoid fever found there. He believed that many of the cases which were named typhoid fever were not that disease at all. There was in India a fever which had no special characters, and which had been named "climatic fever." In the case of many of the new-comers into Hindostan who suffered from typhoid fever it was their own fault that they contracted it. In the case of this form of climatic fever the mortality was by no means so large as it was the fashion to say it was.

Dr. Ferris, of Torquay, said that almost all persons now agreed that typhoid fever was a germ disease. The soil, however, on which the germ fell was of importance. In Hindostan the spread of typhoid was favored by a host of circumstances. The cows in that country were fed on all sorts of garbage, including the fæces of horses, and the milk was watered by the most filthy and polluted water that it was possible to conceive. Even supposing that the milk was pure, the water was horribly the reverse. He agreed with Sir William Moore that many of the cases which was spoken of as typhoid fever were not really cases of that disease at all. With regard to the exposure to the heat being a cause of typhoid in Hindostan, it was merely so because it weakened the patient.

Dr. Seymour Taylor, of London, said that he believed that diseases were apt to present a different aspect in different countries, just as animals did, of which there were different types in hot climates and in cold. Thus the typhoid fever of Germany appeared usually to be of a far graver character than that met with in London. The type of a fever might, indeed, vary in different epidemics. In some cases typhoid would be styled gastric, in others brain fever, etc. He was convinced that in this disease there was, first of all, a germ, and next a receptivity to be taken into account. He compared in this latter point the human race to an army shot at by a shower of bullets, which struck down some, while others escaped. In this way consumption also attacked the hereditarily weak, and those weakened by other causes, and spared the less receptive. The younger the patient the less he was able to resist the germ of typhoid. He believed that as a rule the contagion of typhoid was spread by fluids, but, at the same time, it sometimes was propagated by the air. In the case of a woman, who had been for six weeks in St. Thomas's Hospital, two beds off from a patient with typhoid fever, the disease was taken, and the patient died of it, in which instance he considered that she had caught it by means of the effluvia from the dejections of the typhoid patient in her vicinity. Typhus fever, he thought, might be generated *de novo*, but he doubted that typhoid could originate *de novo*. With regard to treatment, it was curious to observe how many of the patients in the London hospitals had constipation, as compared with patients treated at home. He attributed this principally to the treatment by means of milk, which article of diet tended to produce constipation. He had noticed how frequently relapses of typhoid fever occurred when the patients during convalescence began to take bread and milk. Bread was, he thought, a very dangerous diet in convalescence from such fevers.

Dr. Isambard Owen said that all were agreed that in typhoid fever there were germs. Like germs in the vegetable world, such might fall on suitable soil and flourish, or fall on unsuitable soil and die. Dirty surroundings, everyone allowed, were not conducive to health, and sewage-polluted water was certainly not a desirable drink. He proposed that the following resolution should be passed by the Section: "That the attention of the Parliamentary Bills Committee of the British Association be called to the evidence shown by Dr. Hamilton as to the lamentable frequency of typhoid fever in Hindostan."

This resolution was seconded by Dr. Suckling, and having been submitted by the Chairman, was carried unanimously.

Dr. Hamilton said no words of his could depict the foulness of the milk-supply to the troops in many parts of India. In one place which he inspected the cows were continually dying from pleuro-pneumonia; and, on entering the precincts of the cow sheds, he found these on one side of a yard and the milkers' habitations on the other, the court-yard being covered with the dejections of the cows and the human beings crowded in a small yard. The water in which the pails were washed was in a corner of this foul yard, and into it ran the rain from the yard, carrying the fecal matter into this tank. The milk-pails were crusted over outside with filth, and the whole place was perfectly horrible to enter and to contemplate.

A member remarked that filtering water had no great advantage in many cases. Indeed, in some the filters might introduce disease-germs into water which had none previously. Nothing short of boiling all milk and water would free these fluids from the danger of conveying disease.

A member from Queensland, Australia, wished to hear from Dr. Hamilton his opinion as to the existence of typho-malarial fever. He was himself unable to say whether or not there was such a hybrid fever. Enteric fever in Queensland had many varieties. In response to a question from Dr. Drysdale, the speaker said that typhoid fever was usually brought to Queensland by passengers in ships from England, and not from other colonies.

Dr. Pilcher, of Boston, congratulated his old friend, Dr. Hamilton, on his admirable paper, which would certainly prove of great service to the nation. Many of the ablest men hesitated in pronouncing on a case of typhoid fever, which proved how difficult the diagnosis of that disease often was. He was of opinion that the earth at Lucknow might retain the germs in vitality and be a cause of new cases of the disease.

Dr. Hamilton, in closing the discussion said that, notwithstanding all that had been urged to the contrary, he was persuaded that typhoid fever might originate *de novo* from filth and heat combined. He noticed at Suakim, where 8,000 of the finest troops had been landed, no case of the disease had been generated on the voyage, but soon after residing there it appeared in a terribly fatal form. Now, the troops were picked men, but the soil got so full of fermenting fæces and such effluvia

arose that the disease was generated, he thought, plainly by the external circumstances alone. As Dr. Drysdale had remarked, scarlet fever would not flourish in Hindostan, but died out speedily when isolation was made use of. He could also corroborate the disgraceful state of the barracks at Dublin with respect to sewage and the high mortality of the troops when there. The natives of Hindostan, contrary to the opinion of some authors, suffered from typhoid fever. As to diagnosis, he had seen so much typhoid that he flattered himself he knew the disease when it came in his way. There was very little difference in its appearance in India from that seen in this country, and new medical men, on arriving in Hindostan, acknowledged this. Typho-malarial fever was not used in the nomenclature of the disease in Hindostan. In remittent levers quinine was of service, while in typhoid fever it was of none. In the latter case the diagnosis became gradually cleared up, and was confirmed in fatal cases by post-mortem examination. Simple colic in Hindostan might raise the temperature to 105° F. In the hills the disease closely resembled its types in England.

Experimental Investigations into the Action of Chloroform and Ether was the subject of a paper read by PROFESSOR MCWILLIAM. In these experiments, made on cats, the animal was first of all anæsthetized and then a certain definite amount of air was passed over a drop or two of chloroform contained in a bottle, and pumped into the trachea. Three or four per cent. of chloroform vapor was thus used, and the degree of anæsthesia attained was tested by the conjunctival reflex. In the case of the heart in chloroform inhalation, it was found that there was a tendency to dilatation of all the chambers, which was not seen when ether was the anæsthetic agent made use of. Among the animals experimented upon death frequently occurred from the inability of the heart to carry on the circulation, although the respiration continued for a considerable time. In such cases the heart might still move a little, but its action as a pump had ceased. The fall of blood-pressure when chloroform was administered was protective, if taken in quickly; but in some cases the heart became rapidly affected and the animal died. In reply to a question by Dr. Drysdale, the author said that as far as it was possible to draw conclusions from experiments on the lower animals, ether seemed to be a much safer anæsthetic than chloroform. There was also a curious after-depression in the case of chloroform not met with when ether was used. The measurement of the dilatation of the heart was made by its action on a level resting on it when the chest was laid open.

WHAT SHALL WE DO WITH LINGERING LABORS?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the Section of the British Medical Association on Obstetrics and Gynecology, a most interesting discussion upon the subject of "Management of Lingering Labor," a paper read by Dr. W. S. Playfair, brought out a striking variety of opinion concerning the use of drugs in this class of cases, which, Dr. Playfair was careful to explain in beginning, included only cases not attributable to mechanical obstruction, but simply due to uterine inertia. Dr. Playfair said that in his opinion, based on his own experience and corroborated by the views entertained by the authorities of the leading maternity hospitals of Great Britain, the use of ergot prior to the expulsion of the placenta was practically obsolete. He relies more upon position, pressure over the abdomen, and considers chloral hydrate of drugs the sheet-anchor, to be used up to the time the head presses upon the perineum. Then he uses chloroform.

Dr. T. More Madden said his practice was to use ergot in doses of three to four drachms in the beginning of the second stage of labor, and usually to supplement this with a hypodermic injection of ergotin. Dr. M. Cameron carries two-grain pills of opium in his pocket, and if any delay occurs gives a pill, which he expects will either put the patient to sleep for a number of hours or speedily terminate the case. Certainly a remarkable variance among authorities.

Very respectfully,
GEO. C. MOSHER, M.D.

BIRMINGHAM, July 30, 1890.

Small-pox	0	0
Varicella	2	0
Pertussis	0	8

The Effect of Iced Tea.—Dr. G. W. Barr writes, in the *Therapeutic Gazette*, that iced tea has none of the physiological action of theine if it is kept ice-cold for a short time. He says that he has known a man of nervous temperament, who is kept awake all night by a single cup of tea, to drink a half-gallon of iced tea during the evening and sleep soundly at his usual time of retiring. Others, made very "nervous" by hot tea, have been able to drink large quantities of iced tea with no appreciable effect. If the tea-grounds are allowed to remain in the liquid, the iced tea is usually kept long enough before drinking to dissolve more tannin than is usual in hot tea; hence the tea should be strained as soon as removed from the fire.

The Chinese now Believe in Vaccination.—The Chinese, who reject scornfully nearly every application of Western medical science, are, according to the Governor of Hong Kong, firm believers in the advantage gained from vaccination, and submit to the ordeal with a cheerfulness and philosophy which are characteristic of this wily oriental. Protection by vaccination is especially required in Hong Kong, owing, as Sir William Des Vœux points out, to the frequency with which small-pox is introduced by steamers coming from all parts of the world, and to its fatal prevalence when it has once obtained a footing.

FURTHER OBSERVATIONS UPON FOOT-AND-MOUTH DISEASE IN ITS RELATION TO HUMAN SCARLATINA AS A PROPHYLACTIC.[1]

BY J. W. STICKLER, M.S., M.D.,

ORANGE, N. J.

ON December 1, 1887, a paper upon the above subject was read in the presence of, and discussed by, the New York Academy of Medicine. Since that time I have obtained from Dr. M. K. Robinson, of Dover, England, additional statistics which he has secured for me at considerable personal inconvenience, and which are, I think, of sufficient interest to quote in connection with what has already appeared in relation to the matter under consideration.

First let me review enough of my former paper to present clearly the subject as we are now to consider it.

During the early days of February, 1884, a remarkable outbreak of sore throat occurred in Dover, England, which was due to the drinking of milk obtained from cows affected with foot-and-mouth disease. During the week ending February 9th two hundred and five persons were attacked with the disease. "The majority of persons who suffered during this Dover epidemic presented two prominent symptoms in common, viz., inflammatory sore throat, and enlargement of the lymphatic glands," but the lesions produced varied considerably in different cases. The vesicular eruptions were followed either by a raw red, œdematous appearance of the mucous membrane, or white patches, and the ulcers which supervened assumed in many instances a chronic character, with thick puckered edges, and were a long time in healing.

When the inflammation of the tonsils went on to suppuration recovery was much slower than after common quinsy, and the enlarged cervical glands remained tender, red, and swollen long after the throat symptoms had subsided, *resembling, in this respect, the sequelæ of scarlet fever.* (I am quoting now from Dr. Robinson's original paper on the Dover epidemic). Erysipelas and purulent formations were concomitants also of the epidemic. "In some instances the feet of those who suffered were swollen and painful, simulating rheumatism."

"A fatal termination resulted in the cases of two children, who had very bad throats and mouths, with the extension of the disease, in one case, to the respiratory tract, their deaths being, in the opinion of the medical attendant, due to the poisonous effects of the milk." "Two persons who labored under chronic kidney disease, were respectively attacked with sore throats and died on the same day; other people in the same houses suffering, also, from the epidemic sore throat." "A servant girl was attacked on February 4th with sore throat and pain in the limbs, complained on the 8th of great pain in the epigastric region, and dyspnœa. There was a purple-red patch on the left cheek, extending to the nose. At 3 P.M. on the 9th, she passed into a state of coma, and died at 4 P.M." Mr. Wood says this was an obscure case, but thinks it possible that it was one of blood-poisoning.

Being in England in 1886 to investigate this unusual epidemic of sore throat, and wishing, if possible, to learn what relation, if any, it bore to scarlatina, I went to Dover to consult with Dr. M. K. Robinson. He received me very kindly, and said he would go with me to the various homes where the disease had visited, that we might gain the desired information. The following *facts* were elicited:

1. That members of eight different families who had previously had scarlet fever, escaped the "throat epidemic," while all the other members contracted the disease, all alike having taken freely of milk infected with the contagium of "foot-and mouth disease." The number of those who escaped was 23 +. I say plus 23, because in the case of one family we were told that the father, mother, and servants escaped, the number of servants not being stated. Allowing the number of servants to be two, the whole number would be 25.

2. That of 183 persons who had the "throat epidemic," 16 had had scarlet fever.

3. That 4 of the 16 persons who had had scarlet fever had a mild form of the "throat epidemic."

4. That two of the affected individuals had scarlatina when young.

5. That none of the persons affected with the "throat epidemic" had contracted scarlet fever from natural, accidental exposure, between the time of having the "sore throat" and the date of my visit (1886).

At this point, and in close connection with what has just been stated, let me quote in extenso the paper recently received from Dr. Robinson, the one alluded to in the first few lines of this article. It is as follows:

DEAR DR. STICKLER: I have at last been able to complete the further inquiry which you asked me to make, and beg to furnish you with the information sought for, which you may consider more complete than my previous communication to you upon the subject. The following summary has been compiled from statistics containing all the information procurable concerning the epidemic of 1884:

The number of cases of foot-and-mouth disease which came under observation during an epidemic of this disease at Dover, England, in 1884, was 205. The number of persons attacked who had previously suffered from scarlet fever was 23. The number of persons attacked who had not previously suffered from scarlet fever was 161. The number of persons who, having had scarlet fever and imbibed infected milk, escaped foot-and-mouth disease was 36.[1] The number of persons who had foot-and-mouth disease in 1884, since exposed to scarlet fever without contracting the disease, was 14.

With regard to the prevalence of the disease in Great Britain, it does not appear to have been worthy of recognition in our official nomenclature of diseases, and it has escaped notice by the leading authors of our text-books on medicine. When my interest in this disease, as developed in the human subject, was aroused, I had to resort to veterinary practitioners and veterinary works in order to obtain descriptions of the symptoms, and history of the malady. I am not surprised, therefore, that Sir James Paget should write to you to the effect that he was not aware of the existence of the disease when it fails to find a place in British nomenclature and teaching. It is

[1] Read before the Section on Diseases of Children, at the Forty-first Annual Meeting of the American Medical Association, held in Nashville, Tenn., May, 1890.

[1] This number includes persons other than families in which the disease broke out.

now twenty years ago, when Medical Officer of Health for the Borough of Leeds, that a distinct epidemic of this disease came under my notice. It was confined chiefly to children who had partaken of milk from cows suffering from this disease, and the symptoms in the human subject were most characteristic. Since that time limited outbreaks have, from time to time, come under my observation, which, although clear to my mind as to their nature and origin, were limited in point of number of cases on each occasion.

Then came the sudden and wide-spread diffusion of the disease in Dover, which, with considerable labor, I was able to trace so clearly to its source that I felt it my duty to bring the matter before the medical profession and place on record the facts then elicited.

When the history of this last-mentioned epidemic obtained notoriety from its publication in the daily papers I had many communications on the subject from persons who had evidently sustained practical experience of the disease, but the nature of which had escaped recognition at the hands of medical practitioners. Thus, Captain Reid, of Backsford House, Ashford, says in a letter to me: "Some few years ago, while staying at a fashionable watering-place, my children were poisoned from milk which I ascertained for certain was derived from a cow suffering from foot-and-mouth disease. I at once recognized the disease, because on a previous occasion five of my household had suffered from drinking the milk of a cow belonging to myself which was afflicted with the disease."

Another gentleman told me that, being thirsty, he went into his cow-shed and drank off a glass of milk just yielded from one of his cows, which he found afterward was ill at the time, and subsequently pronounced by the veterinary surgeon to be suffering from foot-and-mouth disease. This gentleman was attacked with bad mouth and throat. Another gentleman said: "When my cows suffered from the disease, my man, along with his wife and family, would persist in drinking the milk from the diseased animals, and they were all attacked with the malady. The Messrs. Crowhurets, veterinary surgeons, wrote me, saying that when attending upon animals suffering from foot-and-mouth disease, the attendants upon such animals had often complained of the same symptoms which were exhibited by the animals in question, etc.

The disease, as it occurs in animals, has been variously described as eczema epizootica, aphthous fever, epizootic aphtha and murrain, and is characterized by fever and a vesicular eruption in the cleft of the hoofs, or in the mouth, with extension into the throat and nostrils. Shivering, and a ropy discharge from the nose, are often noticed at the onset of the attack. When the vesicles are ruptured, ulcers form, or red spots, bare of epithelium, appear with the characteristic soreness which ensues.

The incubation period varies, but animals have been known to suffer twenty-four hours after exposure to infection. Various complications occur and erysipelas and pyæmia have been known to supervene.

The following characteristics were noticed in the human epidemic which occurred at Dover:

Shivering, followed by headache and fever, pains in the limbs, thirst, parched lips and a vesicular eruption on the throat and mouth. A common accompaniment was enlarged cervical glands; many had enlarged tonsils, in some instances proceeding to suppuration. In the *Veterinary Review*, vol. iv., p. 502, and vol. v., p. 187, will be found some evidence furnished by Dr. Balfour and Mr. H. Watson, on the transmission of foot-and-mouth disease by milk to man, and in the same periodical (vol. v., p. 81) Mr. Hislop records some instances of human beings taking the disease by inoculation.

Parkes, in his "Practical Hygiene," says: "There has been much discussion whether the milk from cows with foot-and-mouth disease causes affections of the mouth, etc., in human beings. There are some striking cases which seem sufficient to prove that diseases of the mouth, aphthous ulceration, general redness, diphtheritic-like coating and swollen tongue occur. In the "Proceedings" of the Royal Society for 1881 a new form of febrile disease is described by Dr. Evart, the propagating agent being milk from a dairy near Aberdeen. Gamgee, the eminent veterinary surgeon, says that the disease is communicable to man, as the history of the various outbreaks of disease undoubtedly prove. I have referred in detail to the above-mentioned symptoms as observed by reliable narrators, because I am satisfied that many ill-defined throat affections are due to bovine sources.

During epizootic epidemics I have again and again noticed the concomitant prevalence of aphthous affections and diphtheritic-like appearances, described often under the heads of follicular stomatitis and follicular tonsillitis.

Dr. C. Fox described a peculiar epidemic, characterized by inflammation of the tonsils, extending into the pharynx, and sometimes to submaxillary and cervical glands, and accompanied by yellowish patches on the throat.

This outbreak occurred in October and November, 1875, in a parish which differed from its neighbors in this, that the inhabitants were supplied with water from a stream polluted at various parts of its course by the drainage of farm-yards, the inference being, that the specific poison was derived from the infected excretions of cattle.

That some intimate relationship exists between scarlet fever and diphtheria appears to be extremely probable, my own view being, that diphtheria can be produced by the pabulum on which the scarlet fever poison exists, during the interval between its passage from one human subject to another. I have known instances where diphtheria has broken out at isolated spots in the country when, after diligent search, no exposure to any previous case of diphtheria could be traced, but where I know that scarlet fever had previously occurred, and that those who suffered from diphtheria had been exposed to exhalations from scarlet fever infected excretions. Again, it is the custom in many parts of England to cart town refuse and garbage into the country, and there may be witnessed the disgusting spectacle of swine feeding upon the scavenger's motley collection, including, as such heaps do, not only decaying vegetable and organic matter, but rags and poultices from hospitals and sick-rooms.

Many times has swine fever (which some maintain is allied to scarlet fever) broken out among pigs kept as above described, and I have also noticed that in the same locality the swine fever has been accompanied by foot-and-mouth disease among the cattle, but what is far more important, human beings that have consumed milk from the infected cattle have suffered from diphtheritic-like affections of the throat.

It is a striking fact, that in localities where foot-and-mouth disease has prevailed there also has there been a large development of diphtheria or its congeners.

The cases of foot-and-mouth disease officially reported in England increased from 37,000 in 1882 to 461,000 in 1883, and following this enormous increase of the epizootic disease there was a large increase in diphtheria, the number of deaths alone from this disease in England and Wales during the first quarter of 1884 being 1,270, and the death-rate from the malady higher than that recorded in any quarter of the previous fourteen years. The above observations I have not published, but you are at liberty to make any use of them you think proper.

Believe me yours faithfully,

M. K. ROBINSON.

In immediate connection with this letter, and the statistical table already given, let me call your attention to the facts concerning an outbreak of foot-and-mouth disease in Bethersden, England, in 1884. They are as follows in tabulated form, namely:

No. of cases.	Age.	Scarlet fever previously.	Scarlet fever since.	Remarks by Dr. M. K. Robinson.
1	8	0	0	Members of same family.
2	10	0	0	
3	18	0	0	
4	6	0	0	Members of same family. Four other members, who had previously had scarlet fever, escaped epidemic of sore throat.
5	8	0	0	
6	5	0	0	Same family. Cases 7 and 8 mild sore throat (Dr. Robinson), probably modified by previous scarlet fever.
7	7	1	0	
8	9	1	0	
9	3	0	1	Very slight case of scarlet fever last year.
10	8	0	0	Same family.
11	2	0	0	
12	1	0	0	
13	9	1	0	Same family. Case 13 mild case of scarlet fever. No doctor employed.
14	7	0	0	
15	11	0	0	
16	9	1	0	Same family. Case 16 mild case of scarlet fever.
17	2	0	0	
18	12	0	0	Same family. Three other members of this family, who had previously had scarlet fever, escaped throat epidemic.
19	5	0	0	
20	4	0	0	
21	2	0	0	Same family. Case 22 mild throat case.
22	22	1	0	
23	6	0	0	
24	7	0	0	
25	7	1	0	
26	8	0	0	
27	6	0	0	Case 28 said to have been mild. No doctor.
28	9	1	0	
29	9	1	0	Case 29 mild throat case.

We learn from this table: 1st. That two members of one family who had not previously had scarlet fever developed the foot-and-mouth disease, while four other members who had previously had scarlet fever escaped. 2d. That three members of another family who had not previously had scarlet fever contracted foot and mouth disease, while the three other members who had had scarlatina escaped. 3d. That but one person developed scarlatina after having had foot-and-mouth disease, and that attack was very mild. 4th. That persons who, having had scarlatina, contracted foot-and-mouth disease had the latter affection very mildly. 5th. That these individuals developed the foot-and-mouth disease as a result of exposure to manure derived from cattle affected with aphthous fever.

As supplementary evidence in favor of the prophylactic power of foot-and-mouth disease against scarlatina I will re-state the facts concerning three children whom I inoculated with the virus of foot-and mouth disease.

Case I.—M. M— —, about eight years of age; had never had scarlet fever. On January 12, 1884, I injected under the skin of his arm a small quantity of virus taken from a cow having a mild attack of foot-and-mouth disease. A short time thereafter the cervical glands became enlarged and tender to the touch. There was no marked systemic disturbance, neither was there any sore mouth or throat. All signs of glandular enlargement and tenderness had disappeared in six or seven days. He was then taken to a house in which there was a boy sick with scarlet fever. The disease was in the desquamating stage and the throat still sore. His parents being poor, the pillow upon which the patient lay had not been exchanged for a clean one since the beginning of the sickness. This pillow was placed upon the face of the boy who had been inoculated, and held there some time. He was then made to inhale the breath of the patient, and afterward to remain some time in the sick-room. The boy did not develop scarlatina after having been thus exposed, neither has he contracted the disease since, although there has been opportunity for infection.

Case II.—B. P——, four years of age; had never had scarlet fever. On March 6, 1884, I inoculated her in the arm with a small quantity of foot-and-mouth virus. On March 13th her temperature rose to 103° F. Her mouth was sore without showing any vesicles, and she complained of a pricking sensation in her throat. She had slight headache, the appetite was impaired, and she was quite peevish. There was no eruption at any point on the body. By March 20th she was well. She was then taken to a house where I had a patient in the desquamating stage of scarlet fever. The patient was very sick at the time, because of complications; indeed, was so ill that I was somewhat doubtful about the issue. The same plan of exposure was adopted as in the first case, except that I could not get the inoculated child quite near enough to the patient to inhale her breath; but the "pillow exposure," and the length of time she remained in the sick-room, afforded a good opportunity for infection. She did not subsequently develop scarlet fever.

Case III.—J. M——, about ten years of age. Had never had scarlatina. I inoculated him just as I did the first two. He did not afterward develop any systemic disturbance or local lesion. After a lapse of three years, with opportunity for infection, he tells me he has not had scarlatina.

These cases, taken in connection with the others, suggest gratifying results should further inoculation be made.

In one of my note-books I find this entry, namely: "Thursday, August 19, 1886, went with Dr. Robinson to Canterbury, England, where we saw the health inspector, who told us that in one family the foot and-mouth disease attacked only those members who had not had scarlet fever. We found four persons suffering from the epidemic sore throat who had had scarlet fever."

Without commenting now upon what has thus far been stated, I will describe somewhat briefly (quoting Professor Walley) foot-and-mouth disease as it affects animals.

Synonyms. — Murrain, eczema epizootica, distemper, epizootic aphtha, vesicular aphtha, vesicular epizootic, aphthous fever.

Definition.—It is a vesicular eruptive, or exanthematous affection, due to a specific ferment, and having its lesions localized in the skin and mucous membranes.

Characters.—Eczema epizootica is probably indigenous in the bovine tribe only, but there is no direct proof that it may not originate in the ovine species also. It readily attacks sheep, goats, swine, and poultry; it is easily transmitted to the human subject, and it has been described as existing in the horse, the dog, wild-fowl, deer, wild boar, etc. Walley says little or nothing is known of the ferment of this disease. Dr. Klein, of London, says the disease is caused by a micrococcus which forms in artificial media, besides dumb-bells (diplococcus), beautiful chains (streptococcus). These differ in length according to the number of micrococci composing them, the short chains being a linear series of four, six, or eight micrococci; the longer ones, of more than eight up to thirty and more micrococci. The longer chains are always curved, and even convoluted.

In different outbreaks it localizes itself mainly in the feet, the udder, the mouth, the skin, and mucous membranes, respectively. One attack does not give immunity from others; and not only may an individual animal suffer several times from it in the course of its life, but even twice or thrice in a season, though in a great majority of cases each successive attack becomes milder in its character. Dr. L. McLean, Government Veterinary Surgeon, says, "In the bovine species one attack of foot-and-mouth disease does not give immunity from the disease; but in the ovine species it does."

The channels by which nature endeavors to eliminate the poison, are the salivary and mammary glands, the mucous glands of the bronchial and intestinal mucous membranes, and the skin.

The effects of the poison on the skin are invariably well marked, desquamation of the cuticle being extensive; but while this is a common characteristic of many zymotic diseases, it nevertheless points to the necessity of encouraging the elimination of the poison by this channel.

Period of incubation is, compared with other zymotic affections, short, viz., from twenty-four hours to three weeks. The average is from two or three to five or six days.

Invasion is, on the whole, rapid and pronounced, the

manner of invasion depending upon the amount of poison received into the system, the condition of the host, and the surrounding circumstances.

Duration is variable, and is regulated by the intensity of the attack and the care which is bestowed upon the patient; from ten to twenty-one days may be looked upon as the average period of duration where the disease runs a regular course, and is not succeeded by important sequelæ.

Fatality depends largely upon the character of the outbreak; in some seasons death in any animal is rare, while in others great numbers succumb to the primary effects of the disease.

Propagation.—It is propagated by direct and mediate contagion, as the virus is both fixed and volatile, but it is only diffused through the medium of the atmosphere at comparatively short distances. As the saliva, the nasal, conjunctival, and intestinal mucus are highly charged with the virus, it is readily spread by the conveyance of these secretions to healthy animals, by many direct and indirect means.

Symptoms and Course.—The symptoms must be divided into general, constitutional, and local.

The premonitory constitutional symptoms are identical with those of other zymotic diseases. These are isolation, usually very marked; arched back in cattle; tucked up abdomen; muscular twitchings or shiverings, more or less severe; erection of the hair, the skin being hot and dry; and stiffness of gait, which is most pronounced when the feet—and particularly so if three or the whole — are affected.

Bowels usually a little constipated; urine sometimes scanty, high-colored, and laden with solids, especially as the disease advances; at other times it is profuse and limpid. There may or may not be mucous discharge from the eyes and nose, with increased lachrymal secretion from the former. In young animals, exposed to inclement weather, such discharge is very constant, and in the course of a few days that from the eyes forms a yellow accretion at the inner canthus of the lids and down the sides of the face, a similar accretion being formed by the nasal discharge round the edges of the nostrils.

Under exposure, an irritable bronchitic cough is present, by localization of the lesions in the bronchial mucous membrane. Temperature always elevated to the extent of 2° or 3° F. The pulse and respiration may not be much disturbed. Appetite indifferent when invasion is rapid and the fever high, or the stomach and bowels affected; in ordinary cases, a desire for food is evinced, even though the lesions in the mouth are extensive. In ruminants, rumination is performed naturally, unless the mouth is much affected. In milch animals, interference with the lacteal secretion will be largely regulated by the localization or non-localization of the lesions in the udder. As the disease advances the phenomena above enumerated increase in intensity, and continue to do so until the climax—which may be calculated at from the third to the seventh day—is reached, after which they gradually subside. In addition, vesicular and pustular eruptions may appear on the skin of different parts of the body; they are most often seen in the pig, and the primary may be succeeded by secondary and even tertiary crops.

Jaundice is a very frequent concomitant. Desquamation of the cuticle is an invariable accompaniment of convalescence, the skin being covered with abundant bran-like scales of a yellow color; it is also extremely irritable, animals rubbing against prominent objects vigorously. If the lesions are localized in the gastro-intestinal mucous membranes, colicky pains are induced.

The local lesions are, so far as the skin is concerned, usually seen in parts devoid of hair, or where it is delicate, as the feet, the mouth, the udder, and in some cases the vagina of the female, and the sheath of the male. In all animals the earliest pedal sign is lameness, more or less sudden and severe, with uneasy movements of the limbs. In the course of a few hours, subsequently to the advent of the lameness the vesicular eruptions characteristic of the disease appear. The pedal vesicles are bladder-like elevations, varying in size from a hazel-nut to a walnut. If allowed to remain undisturbed, the vesicles burst in from three to twelve hours and discharge a limpid, colorless, or pale straw-colored fluid; the jagged edges of the lacerated epidermis become retracted and slightly everted, and form an irregularly raised white boundary around the margin of the resulting sore. The cutaneous structure which is exposed by the eruption of the vesicle, is of an intensely scarlet color.

The advent of the mouth lesions in cattle is marked by smacking of the lips, or rather the mouth; by dribbling of the saliva, and by partial or total inability to masticate. The mouth vesicles vary in size and character according to the part of the buccal membrane in which they are located. The pad vesicles appear as flattened elevations of the epithelium, without areolæ around their bases. On the tongue the vesicles are much longer than elsewhere. They vary in number from one to five, and are very resistant. They present much the same character as on the pad. Two or three may coalesce and form one very large vesicle. On the inside of the cheek the reddened condition of the mucous membrane is more discernible, and the resistance of the vesicles considerably diminished. On the lower lip vesication in ordinary cases is comparatively infrequent. The vesicles when they appear are much smaller. On the skin outside the lips vesicles are rarely seen. More frequently secondary than primary, are small and succeeded by pustules and scabs.

In the course of a few days the epithelium will be so far restored as to form a perfect coating over the inflamed tissues. In the cow vesicles usually appear a few hours after the premonitory signs of the disease on the body and around the apex of the teats, but they may be developed in any part of the udder. At first they are discrete, but frequently become confluent. They vary in size from a three-penny piece upward. The period of vesication will vary from one or two to about thirty-six hours, depending upon amount of friction and pressure to which they are exposed. The exposed epidermis, after rupture of the vesicles, is intensely hyperæmic; but if the parts are undisturbed it quickly becomes covered by inspissated pus, coagulated lymph, and epidermic cells—the hair, when present, assisting in forming a coherent brown-colored scab, which has usually irregular edges, and varies in thickness.

The substance of the tongue is usually much more flaccid than normal, and if the papillæ are carefully examined it will be found that, in the earlier stages of vesication, they are much congested, subsequently becoming atrophied and shrivelled. It sometimes happens that when the tongue is seized to explore the mouth large patches of epidermis come away in the hand, as if the tongue had been boiled. This occurs in the aphthous stage, when the vesicles have ruptured, and, the epidermis being removed, erosions appear (Fleming).

Thus far I have simply stated facts, such facts as should receive the most earnest attention of the profession. I make this statement without apology, because I am satisfied that when a disease failed to attack every member of eight different families who had previously had scarlet fever, and attacked every other member who had not had scarlet fever there was some good reason for it—that reason apparently being, not coincidence, but the protective influence of the one disease against the other. Further, not only was this true of eight families in Dover, England, but of two families in Bethersden, England. Again, there were other individuals who, having had scarlatina, escaped the throat epidemic, and as already stated when the "throat epidemic" occurred in those who had had scarlatina, it was mild in character, and in the one instance in which scarlatina occurred after the epidemic sore throat it was a very mild attack. Here again there must be some reason for the mildness of one disease when appearing after the other in the same individual.

Thomas, in his article on scarlatina, says: "Soon, per-

haps already on the second or third day, the entire coating of the tongue with the superficial layers exfoliates, either at once or in successive sections, in a manner found in no other disease." Now here is a disease in which this very thing does occur, as already stated on the authority of Fleming. In both the papillæ of the tongue are swollen and prominent. In both there is abundant desquamation of the cuticle. Sometimes in scarlatina ulcers occur upon the tongue, cheeks and gums, as in foot-and mouth disease. Foot and-mouth disease frequently attacks cattle more than once. Sheep on the other hand do not so commonly have a second attack.

In the case of scarlatina Thomas (Ziemssen, vol. ii., p. 186) says: "As a general fact, it cannot be disputed that scarlatina belongs to that class of diseases which occur but once; nevertheless exceptions appear to be of comparatively frequent occurrence." He then says he collected, in the literature to which he had access, about two hundred cases of a second infection, besides a few reports of a third and fourth infection in the same individual. Murchison observed relapses of scarlatina in two sisters. Trojanowsky says "in two of his cases of secondary scarlatina both parents had also had the disease twice, and in a third case the father had been affected twice." Richardson states that he has experienced scar latina in his own person three times. Sir Robert Gillespie tells of a young lady who had scarlatina three times, the diagnosis of which was unequivocal (Ziemssen, vol. ii., p. 191). Henrici, during the epidemic of scarlatina in Kiel, from 1797 to 1798 attended a woman who was then undergoing her seventeenth attack of scarlatina with all its symptoms (Ziemssen, vol. ii., p. 192). The latter statement may be exaggerated. Dr. Edward J. Ill, of Newark, N. J., writes me as follows concerning some of his own patients: "One of my patients, six years old, had an attack of scarlatina in 1881 In 1883 she had another attack. In January 1887 a third attack. In 1888 she had a fourth attack. Desquamation followed in each instance." Another case, J. G——, aged twelve years, had scarlatina in 1888; had a prior attack in 1881.

The tendency to suppuration of the tonsils and the continued enlargement of the cervical glands in persons who had the foot-and-mouth disease suggested a resemblance of the two diseases (scarlatina and foot-and-mouth disease.) A consideration of the above inclines one to the opinion that the two diseases under consideration may be more closely allied to one another than has heretofore been supposed to be true, and that it is probable that an individual who has had one disease, either will not contract the other on exposure or will have it in a very modified form if he contract it. Dr. Robinson, in a personal letter to me says, "As to the prophylactic power of one disease against the other, my own view is, that if persons who have had one disease and are exposed to the other suffer from the alternate one they do so in a mild form. If there is some intimate relation between the two maladies, it is fair, I think, to assume that persons who have suffered from one form are less susceptible to the other. I do not think I mentioned in my former communications, as evidence of the relation of the two diseases, that in the county of Norfolk, during a period of great prevalence of foot-and-mouth disease among cattle in 1883, there was a great increase of scarlet fever, and especially a scarlatinal sort of sore throat. This fact was stated in the House of Commons during a discussion of the Contagious Diseases (Animals) Bill on March 18, 1884, and reported in the daily papers the following day." Professor Law said, in discussing my former paper: "Epizootic foot-and-mouth disease had at times attacked nearly all the cattle and the people of Great Britain, and considering the fact that the disease was so prevalent, there should be less scarlet fever in Great Britain that in America, where the foot-and-mouth disease is comparatively unknown."

Sir James Paget, in a letter to me upon this point, says: "I have not seen or heard of foot-and-mouth disease communicated to persons in this country." I have asked some of those likely to have known of such cases if they had occurred, but I have learned nothing from them.

Professor Thomas Walley, of the Royal Dick's Veterinary College, Edinburgh, Scotland, says in a communication to me, "Very few people contract eczema" (foot-and-mouth disease). Professor E. Klein, in speaking upon this same matter, says: "My dear sir, In answer to your letter of October 29, 1889, as to whether many of the people of Great Britain have had foot-and mouth disease, I must say that during the nineteen years that I have resided in this country, I have heard of some outbreaks of foot-and-mouth disease among the people in various localities, but they were always localized and did not involve many cases. I must say that I have never been more surprised, than when you told me in your letter that Professor Law offered the remark, that many persons in England have had foot-and-mouth disease. As a matter of fact, the contrary is the case. During the last four or five years, I have not heard of any appreciable amount of foot-and-mouth disease; in fact, I do not think there has been any epidemic of it. I have made inquiries of several friends in the country, and I hear from them that many practitioners have never seen a case in the human, in fact some in practice during the last four years did not know it to have occurred in a single instance in their districts. Only a few weeks back, I had a class in bacteriology at which were twelve gentlemen, in practice as health officers in various parts of England, everyone of them to whom I put your question laughed at the idea that foot-and-mouth disease is alleged to be a common disease in man in this country." These gentlemen evidently do not agree with Professor Law upon the above point. Even if we assume that the disease is more common than it is supposed to be, such facts as are set forth in this paper concerning it, in its relation to scarlatina, have never been noticed or commented upon, and to my mind are not affected by the statement that scarlatina is very prevalent in Great Britain.

Dr. J. Lewis Smith said, in discussing my former paper, "Since the time of Jenner, the hope has been awakened that some of the other fatal infections diseases, and especially scarlet fever, might be prevented, as small-pox has been, by the inoculation of a milder and modified disease derived from the lower animals." Now let me ask my professional brothers, in a spirit of perfect candor and honest inquiry, if in the evidence furnished by the epidemic in England, the *facts* concerning which are herein quoted, we have not a fairly secure basis upon which to build the hope that scarlatina may be either prevented or modified by introducing into the human system, properly prepared and attenuated, foot-and-mouth disease virus. Let me also ask if enough cases have not been quoted, a sufficient number of experiments performed, and the ultimate results of sufficient importance to warrant a more extended trial being made of this proposed method of preventing the development of, or modifying, one of our most fatal and dreaded diseases? No theoretical objection, however adroit and well planned, can settle the question before us; further actual experience with the diseases in their clinical and apparently prophylactic relation to each other must be had before anyone can positively deny, or prove to be true, that which seems to be a fact, namely, that scarlatina and foot-and-mouth disease are mutually protective.

Suppose some drug had been administered to certain members of eight families in Dover, England, prior to the appearance of the "throat epidemic," and that, when those families were exposed to the contagium of the epidemic disease, only those who had taken the drug escaped, while every other member contracted the disease —do you not think the drug would have a new interest, and be given a fair trial, in order to determine beyond dispute whether it would in the majority of cases exercise this preventive influence. Now, why not—instead of saying, How can this be true? or, This cannot possibly be

realized—give the proposed method a fair, honest trial, just as you would give the drug a fair trial, or just as Jenner gave his method a trial, and then be guided in the future by the results. Suppose a certain number of children, in a children's hospital for the treatment of contagious diseases, were inoculated with a modified virus of foot-and-mouth disease, and after recovery from the effects of such treatment should be put into a ward with scarlatina patients and allowed to remain sufficiently long to be thoroughly exposed to the contagium of the disease. Would not that be a fair way to settle the question? What I wish is simply to determine positively, and as soon as possible, whether the escape from the "throat epidemic" of certain individuals, in the two epidemics in England, and of three children from scarlatina whom I inoculated with the virus of foot-and-mouth disease, be due to the protective influence of the one disease against the other, as appears to be the case. If we learn that we may thus prevent the development of a disease so common, ofttimes so fatal, and so frequently followed by distressing sequelæ, will we not confer a blessing on those who are susceptible to its contagium? If, on the other hand, we discover that we cannot, in the majority of instances, confer this immunity, we shall at least have made a commendable effort to realize that which a large number of clinical facts seemed to indicate as possible of accomplishment.

TRAUMATISM OF THE SPINE, WITH THE REPORT OF A CASE OF FRACTURE OF THE SIXTH CERVICAL VERTEBRA, TREATED BY TREPHINING.

By THOMAS H. MANLEY, M.D.,

VISITING SURGEON HARLEM HOSPITAL, NEW YORK.

In the impetuous rush of modern investigation, when the enterprising and ambitious surgeon is anxious to spread his fame, and, besides, honestly strives to make substantial additions to the sum of human knowledge, it is to be expected that exploration, experiment, and observation should be directed to the rachitic region as well as to others.

This, indeed, promised to be a fertile field for the investigator, as for some reason, rather inexplicable at first sight, the past generation of surgeons were singularly chary about invading it; hence, when one sustained a very serious injury of the back, in their time, from violence, resulting in partial or complete palsy, little was done except to enforce rest and subdue pain.

When, however, agents were discovered by the chemist which would annihilate pain and prevent infection, the interdict was set aside, and the hollow cylinder of the vertebral column was no longer regarded as inaccessible to the operator, so that we now read of several operations being performed along the line of the spinal marrow, for traumatisms and pathological lesions with varying results.

The writer at present is mainly concerned in the estimation or the acknowledged value of those surgical measures which involve the mutilation of the soft parts; and with a view of further examining into the alleged analogy of operations on the skull and spine; besides, to submit a few notes on a case recently coming under his care, in which resort was had to active interference. As far as can be ascertained, it is the first and only case on record in this city wherein a fracture in the cervical segment of the spine was diagnosed and treated by trephining, or free incision and removal of the fragments.

History of Case.—The patient was a healthy, vigorous, young Swedish sailor, of more than average height and weight, and of a splendid muscular development.

On the night of May 4, 1890, while ascending a mast, he slipped and fell about twenty feet to the deck, striking on his head posteriorly. He was seen by the ambulance surgeon, Dr. F. P. Hammond, at midnight, and a little later was admitted into Harlem Hospital.

On examination, after entrance, by the house surgeon, Dr. James Guest, his head was drawn back in the condition of most pronounced opisthotonos, the shoulders somewhat raised, with the occiput closely applied to the dorsum. His condition was then supposed to be attributable to dislocation forward of one of the cervical vertebræ. He was extremely collapsed, but had no paralysis at this time. No evidence of serious internal injury was then found.

Treatment.—Heat and stimulants internally were ordered, and in a few hours he rallied well. With the advent of reaction and consciousness he complained of very severe pain throughout the entire neck. Not the slightest movement could be tolerated, even with muscles of deglutition, without great distress. Morphine was freely given. At 8 A.M. he felt comfortable, and desired to urinate, but was unable to do so voluntarily. The first evidence of abolition of the reflexes was with the bladder detrusor.

I saw him for the first time at the noon hour. From a careful examination through the pharyngeal vault I was satisfied that there was no dislocation, and that the clonic contraction of the muscles abont the occiput was spasmodic in character. It was quite evident that there was crushing of the bony spurs—the spinous processes—of either the fifth or sixth cervical vertebra, hence, I ventured a diagnosis of fracture of the sixth. As there were no urgent symptoms, it was determined to wait and act accordingly. At this time, while there was no paralysis of an entire member, yet the grip in the right hand was much weaker than the left, and sensation was somewhat blunted. Toward evening it was clear that the paralysis was deepening, as the reflexes were wholly absent in the arm, and the right leg was quite powerless. On the morning of the second day he had well-marked hemiplegia; little power in the right arm, and none in the left lower extremity.

With this rapidly progressive paralysis, and the source of it so apparent, I resolved to anæsthetize the patient, with the hope of being able to locate and remove the pressure on the cord.

Operation.—Patient was anæsthetized, turned over on his chest, with a padded block under it, and the head extended over the table. An incision was made from the occipital protuberance to the vertebra prominens. The soft parts were infiltrated in every direction with extravasated blood and plastic exudate; the former was found in clots of varying sizes and consistence. The hæmatin in the process of absorption had deeply stained the fascia, intermuscular septa, etc., to a deep brownish-red color. The line of incision was exceedingly vascular, and ligatures had to be applied in every direction before the bony wall of the spine was reached. Owing to the swollen œdematous state of the parts, it was necessary to make a very deep wound. Now, when the tips of the spinous processes were examined a fracture through the posterior laminated arch of the sixth cervical vertebra was seen. It did not appear that the fragments were in the least displaced, their powerful ligamentous support maintaining them in their normal position. But they were compressed in every direction by dense blood-clot, and for the purpose of displacing this I removed both laminæ with forceps and scissors, using the angular rongeur only to nip off sharp projecting spiculæ. Immediately under the blood-clot the bare, white surface of the dura mater was seen.

There was nothing to indicate, from ocular inspection, that integrity was impaired, hence it was left undisturbed. When all oozing had ceased a drainage-tube was introduced into the deep muscular substance on either end; the incision brought together with catgut suture, and antiseptic gauze applied. Over all a cuirass and helmet of plaster of Paris were applied for the purpose of immobilizing the cervical spine.

Patient came out of anæsthesia in fair condition, but had free vomiting. The pain in the neck seemed rather

aggravated than relieved, and the morphine dosage had to be increased. The following morning there was some slight improvement in the paralysis, but the vomiting was assuming a dangerous phase, becoming persistent and projectile. He bitterly complained of the restraint occasioned by the light gypsum cast, especially over the seat of incision. The second night was one of great distress, relief only secured by full narcosis. On the third day he was raised in bed for the purpose of removing the drainage-tube. This was quickly accomplished, but not before he had a short, sharp spasm of the respiratory muscles, when he was promptly placed in the recumbent posture. For a moment it seemed that all was over, as he ceased to breathe, and the radial pulse was gone. Forcible artificial respiration, with the aid of restoratives, however, readily revived him. On the evening of this day he had the Cheyne-Stokes respiration.

The following morning he had a chill, with alarming prostration. It was now discovered that he was having secondary hemorrhage through the opening made by the scalpel. The wound was reopened and packed from the bottom. The hemorrhage was venous and seemed to gush up from every direction. After it was subdued the patient seemed a little easier. As evening approached mortal symptoms became manifest; the pulse became irregular, the extremities cold, and the eyes glazed. He died at 10 P.M., of a general sinking of the vital powers, though conscious to the last.

Autopsy, fourteen hours after death, was made by Dr. Frank Grauer, pathologist to the hospital. Permission was given to only open the spinal canal, hence we were denied the opportunity of examining the organs of the three great cavities.

Blood was found in large quantities along the line of the wound, and when the spinal canal came into view it continued to well up, of a tarry color and consistence, from the inner angle of the deep opening, as if it had been dammed back by compression into the loose connective tissues which line the spinal canal. The muscular and cellular tissues were softened and discolored, with evidences of recent inflammatory exudate. There was a total absence of pus.

Four inches of the spinal cord were removed. On the surface on naked-eye inspection it showed no signs of traumatic or pathological disintegration.

Remarks.—The above was, it seemed, a typical case on which could be fairly tested the practicability and utility of operative interference in traumatic lesions involving this segmented osseous column and its inclosed contents, the cord with its meninges.

At the very outset it is necessary to emphatically deny the claim that the spinal cord is as accessible as the brain, and may be explored with as much impunity.

Even from a surgical stand-point this can be scarcely admitted, though there is absolutely nothing—no organ or structure—which may not be fully and freely explored by the aid of the scalpel, saw, and drill; but physiologically, physically, and anatomically, in the vast majority of cases, division, displacement, or excision is interdicted in traumatisms. Exclusively of the radiating fibres of the temporals the whole vault of the skull is covered by but one broad, thin, ribbon-like muscle, possessing but slight mobility. The whole surface of the skull-cap is quite superficial on the vertex, almost bare when the scalp is removed. There are no movable articulations. Within the calvaria, excepting the longitudinal sinus, there are no venous channels along the periphery of any consequence till we approach the base of the brain. They are all within the dura mater, except the smaller vessels of the diploë, which become usually wholly obliterated in old age.

None of the skull-bones being acted upon independently by muscles it is a simple matter to apply dressings which will insure complete rest. Physiologically the bony inclosure of the skull in the dome—the only part readily accessible to the trephine in fractures—serves but a single purpose, viz., protection to the brain; while the osseous framework of the spine possesses at least three distinct and separate functions: First, to wall in and guard the cord. Second, to support the head, which rests and rotates on the atlas and axis; it also forms the *point d'appui* from which are suspended, directly or indirectly, the cervical structures, the thorax, its framework and contents; all the abdominal viscera, vascular and digestive; and, in the pregnant female, the gravid uterus. Third, it is eminently flexible, in the cervical and dorsal regions especially, being in almost constant motion; it is pyramidal in form, from its base upward, and serpentine in movement and can adapt itself to every diversity of movement, and position. Covered from its base upward along its lateral grooves by powerful muscular, aponeurotic, and tendinous structures, it is nowhere accessible without more or less mutilation of those parts, which in the process of repair, owing to the free plastic exudate diffused in every direction, and never becoming wholly absorbed, leaves adhesions, which later compromise free movement. Hence we find, after incisions into the spinal interior, often a very serious impairment of function, the muscular, tendinous, and osseous tissues being fused together in one immovable, inextricable mass.

The rachidian veins, unlike the main cranial trunks, are external to the dura mater. They have a histological and physiological arrangement peculiar to themselves. They are of large calibre, with very thin coats, entirely wanting in valves, and have several emulgent tributaries. Being wholly independent of atmospheric pressure, circulation within them would be impossible without the suction-power exercised by the respiratory act. Owing to their extreme tenuity and deep cavernous abode, when they give rise to hemorrhage it is extremely difficult, and often impossible, to control. There are, practically, three separate sets of spinal veins, but this is the one which specially concerns the surgeon, inasmuch as it is this set of vessels which invariably is the source of hemorrhage into the spinal canal, which, when in considerable amount, inevitably leads to compression, paralysis, and death.

Hence, in the light of our present knowledge, when from the symptoms hemorrhage into the spinal canal is suspected, absolutely nothing can be done other than to enforce rest and apply remedies which will depress the heart's action, and later promote absorption.

To directly interfere with a view of displacing a clot or closing a bleeding-point is never justifiable in my judgment. The vascular structure of the cord must always escape unless the marrow itself is crushed, when it is not a matter of much consequence. The spinal cord, occupying but two-thirds of the canal, is simply suspended or swung in its tubular chamber, and is stayed in position by its roots, which it gives off through the interosteal notches. No amount of violence or concussion can seriously disturb its vascular supply without laceration or disintegration of its substance. Accordingly, the phrase "free hemorrhage into the cord" must have resulted from careless observation, or an imperfect knowledge of the anatomy of these parts.

The spinal marrow is deeply buried under bone, muscle, and integuments, and around it circulates the arachnoidean fluid which is continuous with the brain. Like the hollow orbit of the eye, the interior of the spinal chamber is lined with a cushion of fat which fills the interspace between membrane and bone, and preserves a moderate uniform pressure on the cord, and adapts itself to its ever-varying dimensions.

Now, when an operation is contemplated which involves the division of the soft parts—muscles, ligaments, etc.—with the boring through or displacement of its bony encasement, with the admission of atmospheric pressure which must violently disturb the delicate arrangement of those structures which connect the corporeal or animal with the mental or spiritual man, we must bear well in mind the possible consequences which, reasoning *a priori*, must frequently follow.

Independent of the immediate consequences liable to follow the free removal of the lateral osseous plates, the

consolidated unified strength of the bony column is forever dissundered. The spine has lost its pristine strength and freedom of motion. No device of art can replace what has been lost. With this gap or fenestrum remaining, the support of the membranes removed, some sort of truss support may become necessary to prevent a prolapse or herniated state of the meninges, and in response to a well-known law in hydraulics, any sudden force applied over the vent must be transmitted through the fluid molecules to the brain.

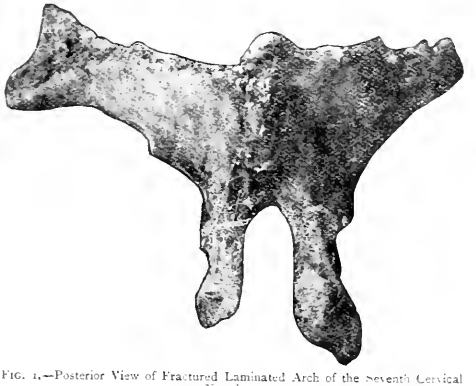

FIG. 1.—Posterior View of Fractured Laminated Arch of the Seventh Cervical Vertebra.

The force necessary to fracture any portion of the spine, particularly in youth and middle age, is very great.

A brochure, the ablest and most exhaustive from an experimental stand-point ever presented by any American surgeon on the subject of spinal injuries, was recently read at the meeting of the American Medical Association, by Dr. B. A. Watson, of Jersey City, N. J. In it he shows us that the violence necessary to fracture the spine of the healthy dog was usually followed by laceration of some vital organ, as the heart, blood-vessels, liver, lungs, or kidney. We may accordingly infer, when a well-marked fracture is clearly diagnosed in any region of the

FIG. 2.—Anterior View, showing the Irregular Fracture through the Centre of Spinous Process.

spine, that some viscus either lying immediately under the seat of fracture, or farther remote, has suffered a serious disorganization by direct or transmitted force. Of the 141 dogs on which Dr. Watson experimented in producing spinal lesions, no less than 119 sustained various associate visceral complications (74.40 per cent.).

Under another course of treatment, on more conservative lines, might not our patient's chances of recovery have been better? I think we may answer this question in the negative, as symptoms which portended a mortal termination were present before we essayed to deal with the case by radical measures, as at this time the reflexes on the right side were wholly abolished and the left lower limb was without sensation. General paralysis was rapidly developing, and bodily weakness was well marked. I am quite sure, however, that the removal of broken bone added nothing to his chances of recovery. The lateral plates, though broken through at the root of the transverse processes on each side, were so held in position by their ligaments that there was but very slight displacement toward the cord. The projectile vomiting, though I have often noticed it before in spinal injuries, was greatly aggravated after operation, and made me suspicious that the descendens noni, or some of the communicating branches of the anterior cervical plexus, were lacerated or divided. I never saw an incision give rise to such agonizing and almost uncontrollable pain.

His attack of nearly mortal collapse on raising the body for the removal of the drainage-tube was an unmistakable warning that the spinal cord and its annexa, the seat of life itself, are not parts to be lightly trifled with.

Death from secondary hemorrhage on the fourth day was the last thing thought of. Hemorrhage welling up from a deeply lodged vessel in the spinal canal is entirely beyond our control, and it is well to bear this in mind when we make an estimate of the dangers in the way.

I have seen, during the past twelve years, many cases of spinal lesions from traumatisms, ending mostly in death, in which, though a few improved, none ever thoroughly recovered who had complete paraplegia on admission to hospital.

In submitting the history of this case, and commenting on questions which must always engage the serious attention of the surgeon who undertakes operations involving the spinal cord, I have endeavored to present the reasons why but little can be expected from procedures which are attended with such dangers as are encountered in this region of the body, or which are very liable to be followed by diminished strength and great loss of function.

A CASE OF ELECTRO-CAUTERIZATION OF THE MIDDLE TURBINATED BONE, FOLLOWED BY MENINGITIS.[1]

BY FRANCIS J. QUINLAN, M.D.,

LECTURER ON DISEASES OF THE THROAT AND NOSE, NEW YORK POLYCLINIC SCHOOL AND HOSPITAL.

IN presenting to the Section the history of this patient, I deem it sufficiently important to detail all the symptoms before and after the operation, in order that a careful and honest review of the case may be had. As far as I know, there is not a case on record in which canterization of the nasal chambers has been attended with fatal results.

I therefore submit to your consideration the following: Ella B——, eighteen years of age, single, dressmaker by occupation, tall, slender, and poorly nourished, came for treatment to the throat clinic of the Manhattan Eye and Ear Hospital, December 29, 1889. The examination, which was confined to the nose and throat, revealed the following symptoms: Obstructed nostrils alternating from right to left, pain over the frontal sinus, smell and taste impaired, discharges scanty, constant dropping of mucus into the throat, huskiness of voice, digestion poor; and she was very nervous.

Diagnosis.—Chronic hypertrophic rhinitis, ecchondroma and exostosis of septum, chronic follicular pharyngitis.

The patient was seen twice a week during the months of January and February, and the hypertrophied inferior turbinated bodies were reduced by the galvano-cautery. The ecchondroma and exostosis were removed with nasal trephine and Bosworth's saw. Great relief to nasal res-

[1] Read before the Section on Laryngology and Rhinology, New York Academy of Medicine, May 27, 1890.

piration followed these operations. Subsequently it was found that both middle turbinated bodies were pressing upon the septum, retaining the secretion, interfering with drainage, impairing the sense of smell, and no doubt causing by pressure the pain referred to in the frontal sinus. It was thought best to remove portions of the redundant tissue. The patient consented, and the alligator forceps was used to do the work. No reaction followed the operations. In a short time the constant dropping complained of ceased, the headache disappeared, and a general improvement in all the symptoms followed. Tonics of cod-liver oil in addition to the syrup of hypophosphites were ordered, and a marked change was apparent. The patient gained flesh, seemed in better spirits, and had the appearance of one much benefited by the treatment.

The above line of treatment was continued during the months of January and February, at intervals of two weeks, thus allowing sufficient time between each of the operations to note if any untoward symptoms should occur. After a lapse of six weeks, during which time the girl sustained a severe shock by the sudden death of her father (who was sick only three days with pneumonia), she called again at the hospital clinic, stating that, although much better, she was not breathing as freely through the right nostril as she had done, and upon examination it was found that the mucous membrane covering the stump of the right middle turbinated body was still too large and pressed upon the septum. Our patient did not look as well as when she last appeared at the hospital; she had lost flesh, was much depressed, had a poor appetite, was restless at night, and on the whole was far from being up to the standard of health. She was told to call in two weeks, and in the meantime to take two milk-punches per day, broths of beef or mutton, and a tonic of iron and strychnine. I believed that her impaired condition was mainly due to the great nervous strain that she had recently experienced by her father's death, and thought nothing more of the matter until she appeared again at the clinic. She was anxious, she said, for treatment, "as she received so much benefit before that she was bound to continue it."

On April 19th, the tissues being thoroughly cocainized, the right medium turbinated body was slightly cauterized with the galvano-cautery. No pain was felt during the operation, the patient brightened up, and returned to her home. Some powders of phenacetine, ten grains each, were ordered to be taken every two hours, should she experience any pain or discomfort. This operation took place Saturday noon.

I was sent for in great haste on the afternoon following, by the mother of the girl, who stated that since her return home she had had frequent attacks of vomiting, and had such pains in her head that she was almost frantic. I found my patient in bed, very much weakened from the constant paroxysms of nausea and vomiting, unable to retain any food, and complaining of intense pain over both eyes. Her temperature was 90° F., skin moist, pulse 100, with occasional beat lost, but still a good pulse for one so prostrate. The respiration was normal, with a marked tendency to sigh; there was the additional symptom of photophobia. Notwithstanding her weak condition she was able to get out of bed and walk into another room, where she remained seated for some time. A hypodermic of Magendie solution of eight minims was given, which appeared to relieve her and temporarily control the vomiting. Sinapisms were applied to the epigastrium and champagne with ice was ordered to be given hourly. I told the family that, as the distance was somewhat great from their abode to mine, if she grew worse they had better summon their family physician, who lived near by.

I heard nothing until Tuesday afternoon (it was Sunday evening when I saw her), when I was informed of my patient's death. This was most unexpected. On Monday morning the family sent for their doctor, who pronounced the case to be meningitis. He had endeavored to control the excruciating pains by the administration of morphine. She succumbed, however, on Tuesday morning, about seventy hours after the operation.

From Morell Mackenzie I quote the following: "But while deprecating unnecessary aggression in this tender region, I do not deny that there are many cases which can only be cured by active treatment, should hypertrophy resist the ordinary measures recommended; the redundant tissues must be destroyed or removed."

Again, in Bosworth's latest edition the following sentence appears: "The galvano-cautery has come into very extensive use, and is warmly advocated by Moldenhauer, Mackenzie, Sajous, Lennox Brown, Seiler, Scheck, Robinson, and others. All these writers give it preference over all methods." Further on in the last-named author's excellent treatise on this subject, he states that "introducing the electro-cautery into the nose involves a certain amount of risk. Most writers recognize, and indeed make special allusion to, the violent reaction that may follow its use, giving rise to an acute and distressing neuralgia, an acute dermatitis, and even an attack of facial erysipelas." However, he records no fatal cases.

Sajous, in his recent work, states that he has never met any untoward symptoms following galvano-cauterization. During the last two weeks I have spoken to many of our eminent metropolitan laryngologists and rhinologists, and they are as a unit in agreeing that grave symptoms have never followed the use of the electro-cautery in the nose, beyond a slight reaction for a day or so.

Carl Seiler, in a recent communication on this subject, states that he has never had a fatal result from the use of the galvano-cautery. In reviewing this case, with its unlooked-for termination, I cannot convince myself that the untimely death of this girl was due *directly* (I emphasize the word) to the cauterization, but to the condition of the patient at the time of this very slight every-day operation. Why did not such a reaction follow the use of the saw (such a case was recently reported by Dr. Baruch with fatal results), or of the drill, the forceps, or even at former cauterizations?

During the three months that she submitted to operations these agents were employed very heroically at times, and still her condition during this period was one of perceptible improvement to the patient and of satisfaction to the attendant. I think Dr. Chappel's paper recently read before this Section is full of interest, wherein direct traumatism in the nasal chambers was stated to have been attended by severe symptoms, many of which lasted for months after the operations.

In dealing with troubles of the nose or throat, requiring the intervention of surgery, I consider it wise, and I would add essential, to obtain, before operating, a thorough and accurate history of the patient. It is far better that the heroic treatment be denied than that the physician should risk the serious reaction likely to follow operations conducted in doubt or ignorance of the physical peculiarities. A person of slender physique may tolerate operations of this character without any serious results, and again, in a person of robust physique the operation may be followed by severe reaction and grave complications. I recommend, then, a thorough investigation, so far as practicable, and desire to record my belief that to the condition of the nervous system at the time of the operation is, in a greater or less degree, due the gravity or danger of the symptoms and consequences that may ensue.

A Coroner's Jury Censure a Physician.—A woman died recently in Omaha from exhaustion following a protracted labor. The coroner's jury found that the woman had come to her death from heart failure, caused by exhausting labor pains and the depressing effects of the anæsthetic. The jury further found from the evidence submitted that the medical attendants upon the case were negligent in their duty in failing to perform the operation of Cæsarean section.

REPORT OF A CASE OF DEFORMITY OF THE SHOULDER.

By JOHN RIDLON, M.D.,

NEW YORK.

CHRISTOPHER K——, aged eleven, referred to me at the Vanderbilt Clinic by Dr. Huntington Richards, presented January 20, 1890. Hereditary history good. General health good. Was a healthy and well-formed infant. During an attack of whooping-cough, when a year old, the deformity which is now present suddenly appeared, and has remained without change since that time. There has been no pain or discomfort at any time. The wood-cuts show the front and back views of the patient at the present time. The chin points to the left, the right shoulder is somewhat raised, and the head approaches it; the sterno-mastoid muscles are equally prominent, and apparently normal. The front view of the patient suggests either torticollis or upper cervical spinal caries. The former is excluded because both sterno-mastoid muscles are equally prominent; whereas in torticollis, with the chin pointing to the left only, the right muscle should be prominent, and that muscle should be structurally shortened, limiting motion as an inelastic band. Upper cervical spinal caries, although sometimes presenting two prominent sterno-mastoid muscles, usually presents prominently only the muscle on the side toward which the chin points—the left in this case—the condition being the opposite of that found in torticollis. Caries is excluded because of the long duration, the absence of pain, and the mobility in the cervical spine.

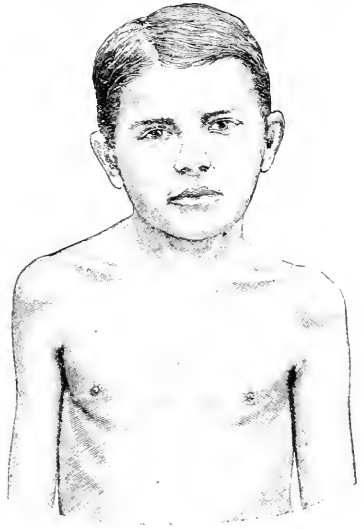

FIG. 1.

Viewed from the back the head approaches the right shoulder, the shoulder is elevated, the scapula is rotated around the shoulder-joint as a centre, so that its lower angle points directly inward toward the spinal column. At the upper border of the scapula a swelling appears, somewhat more than an inch in transverse diameter, and in elevation half that distance; it has a firm, though somewhat elastic, feel. There is no tenderness on palpation, or pain on manipulation of the parts. The case was referred by me to Professor M. A. Starr for his opinion.

In the absence of Professor Starr the patient was seen and hastily examined by Dr. W. W. Skinner, Clinical Assistant to the Department for Nervous Diseases of the Vanderbilt Clinic. He writes: "I have examined the trapezius in question and find that the electrical reactions indicate a very slight degree of degeneration in the fibres of the muscle (the anode producing a slightly greater contraction than the cathode), although both kinds of electricity produce prompt responses. Some of the middle fibres, however, that are inserted into the middle of the spine of the scapula, do not react at all."

On March 21st the case was presented by me, for diagnosis, at the meeting of the Orthopedic Section of the New York Academy of Medicine, with the history as narrated. The notes of the discussion, by the official stenographer, Dr. Ogden C. Ludlow, are as follows: "Dr. Gibney considered it a case of cervical rotary scoliosis, with a cyst at the top of the scapula. He had seen one or two with cysts in that region, and had one at present under treatment in which the cyst had been aspirated, and clear yellowish serum evacuated.

"Dr. Ketch agreed with Dr. Gibney as far as the rotary lateral curvature was concerned. It seemed to him a congenital case, in which there was an arrest of growth of muscles producing the deformity. Concerning the cystic nature of the swelling he was not so positive.

"Dr. Putzell asked upon what Dr. Gibney based his diagnosis.

"Dr. Gibney replied that his diagnosis was made on the position of the right shoulder, and on bending forward there was deviation to the right—right scapula was higher than the other; and the head was drawn a little to that side.

"Dr. Putzell said that it seemed to him that there was a spasm of the muscles inserted into the inner border of the scapula; and that instead of a tumor he found an enlargement of the bones of the inner portion of the spine of the scapula.

"Dr. Judson said that there seemed to be evident scoliosis—a sigmoid curvature of the line of the spinous processes, and also elevation and projection of the right scapula. The tumor he was not so clear about.

"Dr. Birdsall said that the patient had the use of all the different muscles, and the mobility was considerable; but the mass seemed very spherical for muscle, although it changed its shape and hardness with various motions. The electrical test should determine very promptly whether it was cystic or simply due to muscular spasm. The muscular spasm, he should think, would account for most of the deformity.

"Dr. Phelps said that he considered the scoliosis secondary and not primary. The primary difficulty was spasm of the muscles from some cause which threw the head out of line; and the curve had resulted from muscular contraction, which perhaps was, to a certain extent, compensatory. In a growing child, when such a condition took place, scoliosis would result. If there should occur paralysis of the respiratory muscles, we would have an unequal action of the different portions of the chest, resulting in scoliosis.

"Dr. Gray said that he would suggest, in addition to Dr. Birdsall's remarks, that the muscle should be harpooned to determine if there were any muscular degeneration present."

After the meeting the patient's father stated that some two years ago the patient had been anæsthetized by Dr. Gerster, and that the deformity had entirely disappeared, to return again with consciousness. Dr. Gerster says that he saw the patient soon after the deformity came on, that is to say, about six years ago, at which time he anæsthetized him with chloroform and found that the deformity entirely disappeared, but could be produced again at will by the faradic current while the patient was still anæsthetized. He is of the opinion that the deformity was originally due to a paralysis of the serratus magnus, produced during the course of a very severe attack of whooping-cough, and a resulting contracture of the opposing group of muscles, consisting of the rhomboids and the levator scapulæ. Later, it seems, a contraction of the trapezius took place, and a secondary lateral deviation of the spine developed.

Under date of May 16, 1890, Professor Starr, having in the meantime examined the patient, writes: "My diagnosis of the case is a tonic spasm of the trapezius, levator anguli scapulæ, and rhomboidii of the right side, producing a characteristic deformity. It is to be distinguished from paralysis of the serratus by the facts—1, that voluntary contraction is possible in normal degree in that muscle; and 2, that the shoulder is elevated instead of being depressed. The sudden onset, the continued spasm, the impossibility of producing voluntarily a similar position of the left side, the relaxation only under deep anæsthesia, and not in sleep, all favor an organic lesion and negative an hysterical affection. The nerves supplying these muscles come together from the fourth or fifth cervical segment of the cord in the fifth cervical nerve. It seems probable that some irritative lesion there—primarily hemorrhage, secondarily sclerosis—is producing the irritation; the absence of sensory symptoms, of tenderness along the nerves, of muscular atrophy, and reaction of degeneration negative a diagnosis of a lesion of the roots of the nerves

Fig. 2.

themselves. My prognosis as to recovery is bad. Relief could be had by division of the nerves to their muscles individually, but the subsequent paralysis would result in a contraction equally asymmetrical and more inconvenient, and if the divided nerves united or regenerated the symptoms would return. Exercise of the opposing muscles and passive movements are recommended."

On May 24th Dr. Skinner again examined the patient and reports as follows: "Examined by galvanism the muscles of the right shoulder react to this agent in essentially the same manner as those of the left. The trapezius reacts the same on both sides, as do also the supraspinatus and infraspinatus. The rhomboidii, shortened though they were, reacted a little more evidently on the affected side than on the normal side. No difference could be detected in the levatores anguli scapulæ. The serratus magnus on the affected side responded to the stimulus. In sum, there is no paralysis of these muscles, no reaction of degeneration, and C. C. C. > A. C. C. in all, and this is true as well as of the muscles themselves."

Ross[1] says: "Spasm of the rhomboidii manifests itself by the peculiar position of the scapula. Its inner border assumes an oblique position from above downward, and from without inward, the lower angle being drawn upward and approximated to the vertebral column. The muscle can be felt as a firm swelling between the spinal column and the scapula. The affection is distinguished from paralysis of the serratus magnus by the fact that the internal border of the scapula is not lifted away from the chest, the shoulder is not depressed, and distinct resistance is experienced from the contracted muscle when an attempt is made to raise the arm into a vertical position. Tonic spasm or contraction of this muscle has hitherto alone been observed.

"Spasm of the Levator Anguli Scapulæ.—The upper and inner angle of the scapula is strongly elevated in this affection; the head is inclined to the same side; the shoulder is drawn somewhat forward; the supraclavicular fossa is increased in depth, and the contracted muscle projects distinctly beneath the anterior border of the trapezius, which can be easily isolated from it by faradization. It occurs in the form of tonic contracture in connection with spasm of the rhomboidii or of the trapezius."

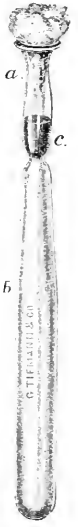
THE USE OF HOT WATER IN THE LOCAL TREATMENT OF ACNE OF THE FACE.

By FREDERICK J. LEVISEUR, M.D.,

DERMATOLOGIST TO ST. BARTHOLOMEW'S AND RANDALL'S ISLAND HOSPITALS, NEW YORK.

Hot water applied twice or three times a day for about five minutes is one of the most reliable local remedies which we possess for the treatment of acne of the face. To derive the full benefit from the effects of this simple remedy it is necessary that the physician, and through him the patient, should be thoroughly familiar with the proper method of using it. The water should be very hot, so hot, in fact, that it can hardly be borne by the patient. Care should, of course, be taken not to scald the face, but if the water is warm only, instead of really hot, more harm than good will be produced. The face should not be washed, rubbed, or bathed with the hot water, as is so frequently done, but a small portion of the diseased area of the face should be soaked with it for a very short time only. The heat of the water, which is brought in contact with the skin, is deeply dissipated for a moment and causes an intense but transitory local hyperæmia. This is exactly what we want to produce. If the hot water is allowed to act on the skin for too long a time, say more than a minute, or if the application is renewed at too short intervals, an acute inflammatory condition is added to the disease already existing. It is sufficient to go over the affected parts twice in one sitting and the entire operation need not take more than three to five minutes. A handkerchief or a piece of soft linen is commonly used to convey the hot water to the face. I use for this purpose a very simple glass holder, which I have constructed. Since this little instrument, which I have named "Thermophor," has proved itself very useful and convenient I shall take the liberty of shortly describing it here.



The instrument consists, as is seen by the accompanying wood-cut, of the handle (*b*) and the head (*a*). The latter is nothing else but an ordinary short test-tube. About half of this tube is filled with cold water (*c*). A thick pad of absorbent cotton is tightly stuffed into the opening of the tube. The holder is then reversed and the water inside the tube allowed to soak the cotton. The latter is thus kept in place by dint of the weight and adhesion of the water. During these few preparatory steps water has been brought to the boiling-point in a small vessel on a stove or over a gas or alcohol lamp. The holder with the

cotton is dipped into the hot water, left in it for a few minutes, and then carefully carried to the affected portion of the face.

The advantages of the "thermophor" are manifold. It saves the patient's hands from coming in contact with the hot water, it renders possible the use of water of very high temperature and makes it easy to confine the action of the heat to a limited portion of the diseased area. Besides it is clean, handy, and cheap.

Not only plain, but also medicated hot water may be used in the manner as described above. Hot solutions of boric acid, bicarbonate of soda, salicylic acid, resorcin, etc., are all very servicable. I have had excellent results, from the use of the so-called "lotio alba" to which resorcin is added according to the following formula :

℞. Zinc. sulf.
Potass. sulfuret..... .. ..āā ʒ j.
Aq. rosar..... ʒ iv.
Dissolve each of the ingredients in half the water, misce et adde

Resorcini..... ʒ j.
S.: Lotion. Shake well.

This lotion is to be used hot at night and cold in the morning.

Clinical Department.

TRANSPLANTING THE FEMURS OF A RABBIT'S LEGS FOR UNUNITED FRACTURE OF THE FOREARM.

By WILLIAM H. SHERWOOD, M.D.,

PAINESVILLE, O.

Some months ago the Medical Record published an operation similar to this by Dr. McGill, of Charing Cross Hospital, London. The radius was the only bone fractured in his case. In this one the radius and ulna were both broken in the right arm, near the junction of the middle and lower third.

January 20, 1890, Mr. A. H—— called at my office to see if anything could be done to restore the usefulness of the member. The forearm and hand were considerably atrophied and the arm was entirely useless, but was not paining him. Although fairly nourished, his appearance was somewhat anæmic. He was unmarried, twenty-seven years of age, a farmer by profession. The injury was caused by falling from a load of hay, the summer previous. Although having been under the care of two excellent surgeons, who had faithfully tried the usual means to bring about union, there had been no effort on the part of *vis medicatrix naturæ* to restore the member. An operation, consisting of transplanting rabbit's bone, was advised. To this he readily consented, and on February 19, 1890, assisted by my friends and eminent surgeons, Drs. O. and F. Pomeroy, of Chardon, O., he was anæsthetized and incisions made. Large quantities of fibrous tissue were removed and the ends of the bones thoroughly freshened. The ends of the radius were quite badly splintered, although not comminuted, but there was as little excision of bone as possible. After arresting the hemorrhage and cleansing the wound with solution bichloride, one to three thousand, at a preconcerted signal Dr. Frank Pomeroy brought in the rabbit's femurs on a plate covered with a cloth wrung out of Peaslie's solution, at a temperature of 78°. The bones were cut into transverse segments about one-fourth inch in thickness. Nine of these pieces were carefully wedged in between the incised ends of the radius and ulna. The wounds were then nicely closed by Dr. O. Pomeroy with fine animal sutures, covered with a thick compress of iodoform gauze, and put up in a firm dressing of silicate of soda, with fenestra opposite each wound.

With the exception of high surgical fever at the end of forty-eight hours, which resembled erysipelatous flush, with a temperature of 104° F., but which, in a day or two, terminated in slight suppuration of the wounds, and a lowering of the temperature to that of normal, there was rapid union of the bones, and a steady improvement in the strength of the arm. About four months after the operation, four of the pieces transplanted were extruded from one of the wounds not quite healed, though both radius and ulna seemed well united.

On August 12, 1890, I saw him for the last time. His arm was firmly united, and he had hired out as conductor of a street car in Cleveland.

I am not aware that the operation of transplanting rabbit bone for ununited fracture has been performed in this country previous to this date.

CASE OF HYPERPYREXIA.

By R. F. GRAHAM, M.D.,

GREELEY, COL.

On April 18, 1890, I attended Mrs. N——, in an easy confinement. The child was a month premature, small and feeble, and very deficient in subcutaneous fat. During the first week it was constipated, made but feeble attempts at nursing, so that it had to be fed mother's milk with a spoon. There was frequent twitching all over its body, and its head was constantly thrown backward. At 4 A.M. on the eighth day I was called hastily to see it on account of its extreme restlessness. The morning was chilly and its room rather cool for comfort. Its respirations were between 70 and 80 per minute, pulse too rapid and feeble to count, temperature in groin and rectum 108.5° F. I afterward tested the thermometer with two thermometers having certificates of accuracy and found it to be correct.

I put the child in a bath at 80° F., at the same time applying cold to the head, and at the end of ten minutes its temperature was below 100° F. Took it out, wrapped it in warm flannels, and it nursed for the first time in several hours, and slept quietly for two hours, the first sleep it had had during the night. At the end of the two hours its rectal temperature was 97.5° F. Gave it stimulants and applied external heat. During the day it had four or five loose stools, but no diarrhœa afterward. Its temperature never rose again above 101° F., and it steadily gained strength from this time on, and is now a nice growing baby at four months of age.

From the time of confinement its mother had no trouble. The child had no inflammation in head, chest, or abdomen, indeed the elevation of temperature was too transitory to be accounted for by any inflammation.

I look on the case as being of nervous origin, possibly a suppressed or aborted tetanus.

THE GASTRO-MUNDATOR.

By JOHN M. THOMPSON, M.D.,

OCALA, FLA.

The introduction of lavage, or washing out the stomach, has proved to be one of the most effective agents in the treatment of the different affections of this organ. By this means we thoroughly cleanse the organ and prepare it for the better application of our remedial agent. Heretofore the application of any of the instruments devised for direct medication of the stomach, through a tube inserted into the organ, has been attended with several objections, the most serious of which was the tube itself. It was hard and almost inflexible, the insertion of which was little more than running a stick down the throat, a treatment which few patients would submit to. Then, after pumping into the stomach the desired amount of water or medicament, the patient had to retain the stomach tube in position until it was unscrewed and attached to the other nozzle on the pump before the contents could

be removed. This procedure in my hands has almost always been attended by such violent emesis that the tube had to be removed before the operation was completed.

The use of the gastro-mundator, an instrument made by Tiemann and Co., which possesses all the necessary requirements for the thorough lavage of the stomach, obviates all the objections to the old instruments used for this purpose. It is quite simple, and consists of a rubber bulb and two tubes attached to the top. One of these is soft, flexible, and velvet-eyed for the stomach, and is as agreeable to the patient as anything inserted into the stomach could be; and the other is a rubber tube of firmer make, which has a metal attachment on the free end, by which the entire contents of any vessel can be drawn up. The soft tube is inserted into the stomach, and the other tube into the vessel containing the medicament, when, by pressure on the bulb, the fluid is injected into the stomach; when ready to pump out the contents, the plate on top of the bulb is simply turned to one side and the same process of pressure on the bulb removes thoroughly the contents. The loss of time necessarily taken to change the tube is thus obviated, and the inconvenience and unpleasant sensation of having a tube down the throat and into the stomach is sooner relieved. The use of this instrument in the different disorders of the stomach, from simple derangement of the digestion to cancer, has proven, in my hands, a valuable adjuvant in their treatment, and I believe it is destined to become more generally used when its true value is known.

Progress of Medical Science.

The Etiology of Asiatic Cholera.—Dr. Hueppe concludes, from his studies and from those of Wood, of Edinburgh, upon the nature of cholera, that it is a process limited to the intestine; it is biologically a specific intestinal putrefaction with the production of a specific toxin. The loss of water and the denudation of the intestinal mucous membrane of its epithelium, though important symptomatically, are without etiological relation to the disease. As far as experiments yet indicate, the cholera bacteria, whether entering the system in a moist or dry condition, and whether inhaled or swallowed, always reach the intestine by way of the stomach. It has been found that with a proper selection of nourishment, but without the presence of oxygen, the cholera bacteria produce their poison more energetically and more quickly than under the ordinary conditions of culture in the presence of air. This is in accord with the fact that the cholera process is carried on in man under the conditions of anaërobiosis. Wood has shown conclusively that bacteria in a state of anaërobiosis are much more sensitive to external conditions than when in a condition of aërobiosis. The cholera bacteria, therefore, though very energetically producing toxin in the intestine, are much more sensitive to external agents, so that traces of acid are sufficient for their destruction. They are more easily destroyed in the fresh stool than at any other time. From a clinical stand-point, therefore, it is important to disinfect the stools and the linen at once, since with delay the resistance of the micro-organisms increases. A therapeutic indication depending on the facts brought forward is to administer by the mouth some substance which may pass the stomach unchanged, and in the intestine act upon the bacteria. For this purpose salol appears to be best fitted, in the effort to exert an internal and perhaps specific action against the disease. These observations account for the hitherto puzzling fact that cholera only seldom is contagious, transmitted directly from the sick to the well. The bacteria are in such a susceptible condition on leaving the bowel, that even if they at once find their way into the stomach of a healthy person, they will almost certainly be destroyed by the gastric juice. In a short time, however, the anaërobic cholera bacteria outside the body, in the presence of air and supplied with proper nourishment, become aërobic. It is also true that the cholera bacteria in the anaërobic condition are much more particular in the choice of their nourishment than when aërobic; and this constitutes another ground for their increased power of resistance outside of the body. The author also maintains that there is a third form—the arthrospores—which is even more resistant than the vegetative aërobic form. In any case, should any of the forms whose power of resistance has been increased enter the stomach, it would seem that they are not destroyed there, even by the presence of acid, but pass into the intestine, and there complete the *circulus vitiosus*. Pettenkofer has, with reason, made prominent the epidemiological observation that, as a rule, the cholera infection is indirect, being influenced by external conditions, the principal of these conditions being the variations in the ground-water. With the diminution of the ground-water—*i.e.*, with the diminution in the degree of dampness in the upper layers of the ground, the danger of cholera increases; while with the increase of dampness in the upper layers the danger decreases. The proper explanation of this would appear to be that the cholera germ enters the ground in its most sensitive and least resistant condition. If too much moisture—*i.e.*, too little air and atmospheric oxygen—is present, they simply perish. If the ground is only damp, so that air can reach them, as aërobic they increase at the expense of the nutrient matter present. If now, with these viable cholera germs in the ground, the ground-water diminishes, the conditions are those most favorable to aërobic life, and the cholera germs increase. The preliminary conditions are thus fulfilled for a miasmatic spread of a cholera epidemic. If, on the other hand, while an epidemic is in progress the ground-water increases in amount, the bacteria can no longer increase, and are either destroyed or rendered inactive, and the epidemic ceases for want of suitable infectious material. Of course, these bacteriological facts are not the only epidemiological factors; but the conclusion seems justifiable that Asiatic cholera is truly a miasmatic-contagious disease, with epidemiologically marked prominence of the dependence upon external circumstances, the nature of which bacteriologically has now become clearer.—*The American Journal of the Medical Sciences*, July, 1890.

Gurjun Oil as an Expectorant.—Gurjun balsam, or wood oil, is a balsamic exudation obtained from the trunk of dipterocarpus turbinatus and other species growing in the East Indies, by incision and the application of heat. It is a transparent liquid, like olive oil, of an opaque, dingy, greenish-gray color, as seen by reflected light, and having an aromatic odor and taste not unlike that of copaiba, but without its acridity. Some years ago it was brought into notice as a remedy for leprosy. In the present instance it was given by Dr. Murrell, for its expectorant qualities, in the treatment of bronchitis and winter cough. At first he prescribed it in doses of one or two drachms three times daily, in combination with liquor potassæ, spirit of nitrous ether, mucilage of acacia, and cinnamon water; but this was not a very inviting preparation, as it had a tendency to "curale" and produce a rash during its elimination through the skin. After a time he gave it with extract of malt—two drachms of the balsam to one ounce of the extract—three times a day, and this was taken without any difficulty. The chronic bronchitics reported that it acted admirably as an expectorant, "clearing the chest" and easing the cough. In several cases pilocarpine was given at bed-time, to produce sweating, but no eruptions resulted. Dr. Murrell concludes that gurjun oil has all the advantages of copaiba as an expectorant, without the grave disadvantage of exciting an eruption.—*The Lancet.*

Typhoid Fever and Diphtheria in Australia.—In Melbourne, Australia, during the first four months of 1890, there were 303 deaths from typhoid fever, and 177 from diphtheria.

FOOT-AND-MOUTH DISEASE IN ITS PROPHYLACTIC RELATION TO SCARLATINA.

IN the interesting paper on this subject which appears in another column, Dr. Stickler presents some very suggestive points which are well worthy of the earnest and thoughtful attention of the medical profession. It will be observed by the reader that no attempt is made in the paper to twist the facts in order to make them fit a pet theory of the author, but they are simply recorded as they were elicited by two observers, and are accompanied with comparatively few comments. The question is then asked, "May it not be true that these two diseases (foot-and-mouth disease and scarlatina) may be mutually protective?" In order to get at the pith of the paper we may reproduce here the main points brought out by the author in his argument. They are as follows:

First, in reference to the Dover epidemic: 1. Members of eight families who had previously had scarlatina escaped the foot-and-mouth disease (or the "throat epidemic," as it was called). 2. Of 183 persons who suffered from the "throat epidemic" 16 had had scarlatina. 3. Four of the 16 who had had scarlatina had a mild form of the "throat epidemic." 4. Two of the affected individuals had had scarlatina when young.

Second, in regard to the epidemic at Bethersden: 1. Two members of one family who had not previously had scarlet fever developed the foot-and-mouth disease, while four members of the same family who had previously had scarlatina escaped entirely. 2. In another family three members who had not had scarlet fever contracted the foot-and-mouth disease, while the three other members, who had previously had scarlatina, were not attacked by the "throat epidemic." 3. But one person had scarlatina after having had foot-and-mouth disease, and in that one the attack was very mild. 4. Persons who had had scarlatina and subsequently contracted the foot-and-mouth disease suffered from a very mild form of the latter affection. It is also stated as a fact that fourteen of the persons who had suffered from the "throat epidemic" in 1884 have since been exposed to scarlatina without, however, contracting the disease. Statements such as these ought not to be put aside as unworthy of consideration, for the facts given are too suggestive of the possibility of a great discovery. Anything that offers us even the hope of preventing the occurrence of such a destructive malady as scarlet fever is worthy our careful consideration.

As will been seen also, on a perusal of the paper, some inoculation experiments were actually made, with apparent success. Three children were inoculated with the foot-and-mouth disease and were subsequently exposed to the contagium of scarlatina, but all escaped infection. Of course such a limited test as this proves nothing, but it certainly suggests the possibility of greater success, and should encourage further trials.

We may also note here what Dr. Robinson says, in a letter to the author of the paper, in regard to the degree of protection apparently afforded by foot-and-mouth disease. He writes: "As to the prophylactic power of one disease against the other, my own view is, that if persons who have had one disease and are exposed to the other suffer from the alternate one they do so in a mild form." He also says, as evidence of the relation of the two diseases, that in the county of Norfolk, during a period of great prevalence of foot-and-mouth disease among cattle in 1883, there was a great increase of scarlet fever, and especially a scarlatinal sort of sore-throat.

Dr. Stickler also makes some interesting statements in his paper in regard to the comparative pathology of the two diseases. In both, it seems, there is enlargement of the papillæ of the tongue; in both there is desquamation of the cuticle during convalescence; in both the period of incubation is of about the same length; and in both there is occasionally a separation of the mucous membrane of the tongue in pieces of greater or less size. These are certainly striking points of similarity.

The fact that absolute protection was not obtained in all the cases thus far observed should not discourage further investigation. Reference to the early history of Jenner's inoculations with the virus of cow-pox discloses the fact that although in the majority of instances immunity from small-pox was secured by the practice of vaccination, yet there were many failures. Several persons who had been successfully vaccinated by Jenner himself subsequently developed small-pox, and some of them came near dying of the disease. Yet no one thinks of doing away with vaccination because it did not always then, and does not in every instance now, protect the human system from small-pox. Even a previous visitation of true variola, measles, or scarlet fever does not render the individual perfectly secure from a second attack of the same disease.

Although we cannot yet accept the facts given as conclusively establishing a mutually protective relationship between the two diseases studied by Dr. Stickler in his paper, yet the evidence adduced seems to us sufficiently strong to warrant further investigation, and even to inspire a hope that these investigations may not be without fruit of real and lasting importance to the human family.

A NEW METHOD OF PRODUCING ANÆSTHESIA WITH CHLOROFORM.

THERE is a determined effort being made by some of the younger French surgeons to introduce a so-called new method of administering chloroform for purposes of surgical anæsthesia. This new method has as its basis the

principle of giving small and continuous doses. It is not in reality new, but is a plan which has never been widely adopted, nor received the recognition which it is believed that it deserves.

The method was described in detail by Dr. Léon Labbé, in 1881, before the Académie de Médecine. In 1883 Dr. Peyraud, of Bordeaux, described a similar procedure and insisted, in several communications, upon its advantages.

In 1887, Dr. Paul Boncour, a pupil of Labbé, described the method again; and M. Péraire, another pupil of Labbé's, introduced it into the service of M. Terrier at the Hôpital Bichat. Last year M. Schwartz again called attention to Labbé's procedure in the *Revue Générale de Clinique et de Thérapeutique*. Now, M. Marcel Baudoin, lately of the Hôpital Bichat, has given another full account of it in the *Gazette des Hôpitaux*.

The very great delay shown by surgeons in recognizing this method of Labbé's indicates, possibly, that it has some radical defects; or it may only show the very pronounced conservatism of surgeons in matters of routine practice.

The details of the process of anæsthetizing patients by continuous small dosage are described by Dr. Baudoin with great minuteness, and every possible precaution in case of accident is taken. The "manuel opératoire" thus furnished is a most excellent one, and ought to be read by every young surgeon and many of the older members of the profession. As regards the administration of the chloroform itself, the process is very simple. No apparatus or special inhaler is employed. A folded handkerchief is laid upon the face carefully, so as to cover the nose and mouth. It is pulled up a little in the middle so as to make a kind of cone. Then, two, three, or four drops of chloroform are poured on the handkerchief, the face being carefully watched for signs of reflex syncope. It may be necessary at first to raise the handkerchief for a moment, but after the first inhalations this should not be done. At the end of a quarter of a minute, four or five more drops are allowed to fall upon the most elevated part of the handkerchief. At the end of half a minute more four to six drops are poured out. This process is continued for fifteen or twenty minutes, when the patient will be anæsthetized. Only seven or eight grammes of chloroform will have been used, whereas by other methods twenty to thirty grammes are usually required.

HYDROPHOBIA BEFORE AND AFTER PASTEUR.

THE daily press is doing much harm in giving dangerous prominence to sensational reports about persons bitten by all kinds of rabid animals seeking relief at the New York Pasteur Institute. The following paradox already confronts us: Rabies increases *pari passu* with the erection of institutes intended to prevent it. Is it not time for our authorities to interfere, and restore the *statu quo ante*, when reporters' quills had not yet succeeded in converting a merely potential danger into a decidedly actual one? A fear-stricken community will doubtless supply as many alleged hydrophobia cases as any number of Pasteur Institutes are willing to accommodate. But the real danger for "the bitten" generally first begins with hearing or reading about the dreadful fate that awaits them. If the public press is really the public's friend, it can perform its high office in no better way than by a studious avoidance of any allusion to hydrophobia for the next ten years. Prurient curiosity need not be catered to by decent journalism.

In the matter of hydrophobia we at present still deplore the absence of reliable records, culled from scientific journals. Unimpeachable testimony, numerically insignificant though it may appear, is therefore to be welcomed by all whose sole interest should be the greatest good to the greatest number. This kind of testimony is found in the *Journal de Médecine de Paris* of July 6, 1890, in a brief article from the pen of Professor Michel Peter, an author of unquestioned reputation even on our side of the Atlantic. The article referred to contains the official figures of deaths from rabies for the past ten years, as compiled by the authorities of the city of Paris. It appears therefrom that in the most populous province of France, the Department of the Seine, thirty-eight deaths from rabies occurred in the four years preceding the opening of the Pasteur Institute. But in the four years during which protective inoculation has been practised the deaths from hydrophobia amounted to thirty-seven. "Is it possible to furnish a more striking proof of the utter futility of the Pasteur method?" asks the author of the paper under consideration.

Again, according to the figures given by Dr. Dujardin-Beaumetz, a friend of Pasteurism, six fatal cases of rabies occurred in the city of Paris in 1889. Of this number three were treated by protective inoculation, and the other three did not present themselves at the Institute. Dujardin-Beaumetz himself, although an ardent advocate of this blundering system, is compelled to admit that "the Pasteur treatment does not prevent the occurrence of hydrophobia, to suppress which it will be necessary to rigorously carry out the provisions of the law." (Those provisions apply to the muzzling of dogs, and the immediate killing of all animals bitten by others suspected of rabies.)

"*Alors, à quoi bon, Pasteur?*" aptly remarks Dr. Peter.

But the author goes further than this. The official figures evidently show that, with or without Pasteurism, the mortality from rabies remains the same. But, he says, how about those who succumb under protective inoculation, and in consequence of the same? How about those who are sent to their doom ticketed as having died from "pulmonary congestion," when the true cause of their death was antirabic poisoning? There are no figures now to tell these tales. But perhaps some day they will be made public, and then the daily press can be relied upon to raise as much of a hue and cry about the pernicious effects of popular medical illusions as it does at present concerning the marvellous results of treatment at the Pasteur Institute.

The Good Effects of Vaccination have been well shown recently in Holland. During the years 1870–1873, 20,575 persons died of small-pox in that country. Since then as a result of the strict enforcement of the new vaccination laws, the prevalence of the disease has steadily declined. Last year but a single death occurred from small-pox in the entire kingdom.

News of the Week.

An International Congress of Vegetarians was held in London on September 11th, 12th, and 13th, in Memorial Hall, under the auspices of the Vegetarian Federal Union.

Influenza still Rife.—Reports from various places in Europe state that the influenza is still prevalent, though with different symptoms from those most commonly observed during the epidemic of last fall and winter. In some places the most prominent symptoms are those of gastro-intestinal disease, in others a simple mental and physical depression, and in still others a severe form of pharyngitis. It is very questionable, however, how far these little local epidemics, with such varying symptoms, can justly be attributed to the action of a common cause, whether influenza or any other specific disease. Sore throats, diarrhœas, and nasal catarrhs are common enough at all times, independent of any special epidemic influence. In Iceland, however, the genuine disease seems to be prevailing in an aggravated form. It has appeared in the island and has spread with great rapidity. Former epidemics of influenza in Iceland were very fatal. In 1843, in a total population of 57,000, the deaths from influenza amounted to about two thousand, and in 1866 there were nearly fifteen hundred deaths from the same cause. The *Correio Medico*, of Lisbon, states, only recently, that influenza has also been rife at the Azores for some months, and that it seems to be assuming a more serious type.

Opium Production in China.—The Emperor of China has issued a decree legalizing the production of native opium. As the total annual home consumption of opium in China has lately been reckoned to be about forty-one million eight hundred thousand pounds, it is expected that this will in future be a source of considerable revenue to the imperial exchequer.

Small-pox is said to be prevailing to a very alarming extent in Saltillo, Mexico. The local authorities have taken no measures to prevent the spread of the disease. The mortality is chiefly among children, as many as four hundred of whom have died within a single month.

Appointment of a Woman Interne in Brussels.—A Miss Everaert, who was recently graduated with high honors from the medical school at Brussels, has been appointed Assistant Physician to the Hôpital St. Jean in that city. This is said to be the first time that a staff appointment in any of the public hospitals of Belgium has been conferred on a woman.

Increased Powers to Health Boards.—A law has recently been passed in England giving to the health authorities power to tear down any building which may be deemed injurious to public health, and also to regulate the number of inmates of any house.

The Journal of the Arkansas State Medical Society made its first appearance in July. It was started at the suggestion of Dr. Orto, who made a strong plea for it in his presidential address at the last annual meeting of the Society. It is proposed to issue the journal on the 15th of each month, and we are pleased to learn that the venture is already established on a firm financial basis.

Cœliotomy is the name which Dr. Robert P. Harris, of Philadelphia, says should be used as the synonym of abdominal section, the term laparotomy being applicable only to an incision in the flank. He has written a pamphlet in support of his position, wherein he adduces many arguments in favor of the use of this word, incidentally giving the time-honored and trusted Kraus a blow which well-nigh topples him off his pinnacle of fame as a learned dictionary-maker.

The Pourrat Prize.—Professor Johannes Gad and Dr. François Heymanns, of the Physiological Institute attached to the Berlin University, have received the Pourrat prize of the Paris Academy of Sciences for an essay on the influence of temperature on the functions of the muscular tissue.

Scurvy in Newfoundland.—This disease is reported to be alarmingly prevalent among the fishing towns of the French shore of Newfoundland.

The Paris Night Medical Service in the course of the last year paid 2,135 visits; the preceding year the number was the same. The proportion of male patients was thirty-three per cent., of female fifty per cent., and of children under three years of age seventeen per cent.

Prizes for Essays on First Aid to the Injured.—The French Society of Hygiene offers a gold medal of the value of $40, a silver medal, and two bronze medals for the best essays on the following subject: "The Treatment to be Carried Out before the Arrival of the Doctor in Cases of Accident Occurring in the Street or in Workshops." Particulars may be obtained from the Secretary, 30, Rue du Dragon, Paris.

An International Sanitary Commission.—Premier Crispi, of Italy, has just caused to be distributed to the representatives of Italy in foreign countries a circular, in which he proposes the convening of an International Commission with a view to institute a sanitary service for the Red Sea. He suggests that two international sanitary offices be established, one for the medical visitation of ships which enter the Red Sea from the Indian Ocean, and the other for that of ships which pass from the Red Sea to the Mediterranean. Another proposal in his circular is to the effect that in connection with each of the two offices should be instituted an international sanitary station, where the ships must put in for disinfection when found to have cases of infective disease, actual or suspected, on board.

Notification of Infectious Diseases in Milan.—The Mayor of Milan has sent a circular to all the medical practitioners in that city urging upon them the strict observance of the new Italian law as to the notification of infectious disease. The diseases to which the enactment applies are measles, scarlet fever, small-pox, typhoid, typhus, diphtheria, croup, puerperal fever, hydrophobia, cholera and other possible diseases of exotic origin transmissible or suspected of being so, and syphilis conveyed by wet-nurses.

Selling Bodies to Medical Schools.—The grave-digger of a Chicago almshouse has been discharged for disinterring the bodies of paupers buried in the infirmary cemetery and selling them for $25 apiece to certain physicians.

Dr. Israel I. Buckbee, of Fonda, N. Y., celebrated his golden jubilee of medical practice on September 10th, the event being marked by a banquet given him by the Montgomery County Medical Society.

An Army Medical Board will be in session in New York City, N. Y., during October, 1890, for the examination of candidates for appointment in the Medical Corps of the United States Army, to fill existing vacancies. Persons desiring to present themselves for examination by the Board will make application to the Secretary of War before October 1, 1890, for the necessary invitation, stating the date and place of birth, the place and State of permanent residence, the fact of American citizenship, the name of the medical college from whence they were graduated, and a record of service in hospital, if any, from the authorities thereof. The application should be accompanied by certificates, based on personal knowledge, from at least two physicians of repute, as to professional standing, character, and moral habits. The candidate must be between twenty-one and twenty-eight years of age, and a graduate from a regular medical college, as evidence of which his diploma must be submitted to the Board. Further information regarding the examinations may be obtained by addressing J. H. Baxter, Surgeon-General U. S. Army, Washington, D. C.

Dr. Robert Alexander Manwaring, of New London, Conn., died on September 1, at the age of seventy-nine years. He was born on August 11, 1811, and was descended from two old colonial families. His father was a friend of Jefferson and Jackson, and his mother was Mary Wolcott, granddaughter of the Oliver Wolcott who was a signer of the Declaration of Independence. Dr. Manwaring was a classmate of Oliver Wendell Holmes, and they always kept up their school time friendship. He was, for nearly fifty years, one of the leading physicians of Eastern Connecticut. He married Ellen Barbour, daughter of Congressman Barbour, of Conneticut. She and one son survive him. Dr. Manwaring was a true type of the old-time family practitioner; not learned, in the modern scientific acceptation of the term, but thoroughly practical, and always well up to the latest advances in medicine. He was a gentleman and a conscientious physician, and of a most kindly disposition, very modest and retiring, yet not afraid to maintain his views when he believed he was right.

A New Hospital Building in Cleveland.—Plans have been drawn for a new building for St. Alexis Hospital, in Cleveland. The hospital is under the care of the Franciscan Sisters.

The Pennsylvania and Maryland Union Medical Association held its thirteenth annual reunion at Highland Park on August 28th.

The Mountain Side Hospital is the name of a new hospital which it is proposed to erect in Montclair, N. J. The towns of Bloomfield, Caldwell, and Verona will be interested with Montclair in the establishment of the institution. It is proposed to locate it on or near the township line of Bloomfield and Montclair. It is to be governed by a board of managers of twenty-one ladies from Essex County.

Yellow Fever at Port Limon.—The New Orleans Board of Health recently called the attention of the State Department to a report that yellow fever was prevalent at Port Limon, Costa Rica, and that the United States consular agent at that port had neglected to report the disease. A reply was received from Acting Secretary of State Wharton, acknowledging receipt of the Board's communication, and stating that the consul at San José had been instructed to investigate the matter. The report of the latter has not yet been made public.

Foreign Medical Students in Paris.—During the school year of 1889–90 there were 822 foreign students in the medical school in Paris. Of these 6 were German, 51 English, 7 Austrian, 7 Belgian, 8 Bulgarian, 34 Spanish, 34 Greek, 6 Dutch, 12 Italian, 18 Portuguese, 85 Roumanian, 261 Russian, 20 Servian, 25 Swiss, 71 Turkish, 159 American, 10 Egyptian, and a smaller proportion of Swedish, Persian, and Australian students.

A Strike of Hospital Internes.—The house-surgeons, dressers, and other students holding hospital appointments in Ghent have "struck" in consequence of the insulting treatment of the directors and council of the hospitals. This action of theirs was taken with the approval of the staffs of the hospitals, most of the members of which are professors or lecturers appointed by the University. The "striking" students, not wishing that any harm should happen to the patients, seem to have offered the council to carry on the necessary work pending the settlement of the dispute. Indeed, all that they demanded was that in the future they should be responsible to the permanent professional staff only. However, the council immediately issued notices inviting applications for the vacant posts. There being a thoroughly good understanding between those who resigned and the other senior students, it is unlikely that a single one of the latter gentlemen will accept any of the posts. The same remark applies to the junior practitioners in the town, and to the men recently qualified who still frequent the hospital.—*Hospital Gazette.*

A Fat Woman.—A girl, aged nineteen, and weighing 470 pounds, has recently died in the quartier de Plaisance, Paris, from an attack of erysipelas. She was 5 feet 7 inches in height, and measured 88 inches around the waist, 35 inches around the arm, and 42 inches around the thigh at the junction of the upper and middle third.

The Béhies Pathological Prize.—The Faculty of Medicine of Paris has been authorized to accept a legacy of 30,000 francs bequeathed by Madame Béhies to found a biennial prize for the best work on a given question of medical pathology.

Dr. Charles Steel Thomson died recently in New Haven, in the ninetieth year of his age, having been born in Tolland, Conn., April 6, 1801. His father, Dr. Gurdon Thomson, was a noted physician one hundred years ago and more, and was an earnest advocate of the cottage system of treatment for the insane. Dr. C. S. Thomson studied medicine at the Yale Medical College, from which he graduated in 1822. Since the death of Dr. John A. McLean, of Norwalk, in 1883, Dr. Thomson has been the oldest living graduate of this department of the University.

The Cholera.—Asiatic cholera now prevails over a pretty large area of the earth's surface, and seems to be increasing steadily both in its intensity and in its extent. It is reported from Spain, Portugal, Egypt, Turkey, Arabia, Southern Russia, Japan, and Batavia. In Spain there are at least five provinces, namely, Valencia, Toledo, Alicante, Castile, and Badajoz, in which the disease exists, and in Portugal the government reluctantly admits that three districts are infected. From Mecca news of the presence of cholera was first received about the end of July, and although quarantine was at once established against the pilgrims returning to Cairo, it was ineffectual or too late, for the disease broke out with considerable violence, and spread thence westward along the shore of the Mediterranean. It is said now that Mecca is free from the disease. In Japan the epidemic is in full sway in many places, Nagasaki being reported as specially afflicted with the plague. France is making special efforts to keep the cholera away from the southern departments, and the French Senate, on August 4th, voted 100,000 francs for the establishment of frontier posts to prevent the entry of cholera into the country. A decree has been passed by the government making it a criminal offence for anyone entering the country from Spain to fail to notify the authorities of the fact. Several Spaniards, among them many ladies and children, have been apprehended for failure to comply with this decree, and have been condemned to varying terms of imprisonment (usually three days) and to pay fines of from one to ten or fifteen dollars. In Spain the physicians are having the usual trouble with the peasants, who oppose all attempts to improve the sanitary condition of the towns, and in some places the peasants have been so threatening in their attitude against the physicians that the latter have been compelled to appeal to the authorities for a military escort. Considerable uneasiness was caused not long ago in London by the report that a patient in the Poplar Hospital was suffering from Asiatic cholera. Upon careful investigation, however, it was determined that the case was simply one of aggravated cholera nostras.

The Association of German Naturalists and Physicians will hold its sixty-third annual meeting in Bremen, on September 15th, continuing in session the entire week. Some doubt has been felt as to the ability of those taking part in the meeting to secure suitable accommodations, all the hotels in Bremen being filled at this time by returning Americans.

A New University in France.—The General Council of the Haute Garonne has drafted a petition for the establishment of a university at Toulouse, and the mayor of that city has opened a subscription list for the benefit of a medical faculty to be attached to the university.

Intestinal Antisepsis in Apiculture.—It is stated in the *Lyon Médical* that a Mr. Lortet, of that city, has just made a successful experiment with the use of naphthol to destroy the bacteria which develop in the intestine of bees, and cause the disease known among apiculturists as "la loque." Thirty-three centigrammes of naphthol is dissolved in a litre of syrup, to which one gramme of alcohol has been added to facilitate the solution. This syrup is given to the bees in the spring, and often prevents the epidemics which have destroyed so many hives.

Disinfecting Cattle-cars.—The police prefecture of the Seine has ordered that all cars used for the transportation of cattle to the abattoirs of Paris shall be thoroughly disinfected after each trip. The process of disinfection is carried out under the supervision of four veterinary inspectors, and is effected by thorough washing of all parts of the cars with a two per cent. solution of sulphate of zinc.

Leprosy in India.—The question of the proper housing and care of lepers is attracting much attention in India. A public meeting has been held at Bombay, and a committee appointed to consider the matter. The Calcutta Health Society has also addressed the Government, urging the necessity of legislation, and pointing out that all leper asylums should be scientifically regulated, and should be under government control.

Enforcing the Registration Laws.—The Pittsburg Board of Health has recently sent out a circular to the physicians, clergymen, and undertakers in that city, calling their attention to the existing law regarding the compulsory registration of births, marriages, and deaths. The Board proposes in future to enforce the legal penalties for neglect to comply with this law.

Child Suicides.—Since January 1st, 62 children, 46 boys, and 16 girls, have committed suicide in Berlin. Of this number 24 had attained the age of fifteen, 14 their fourteenth year, 9 their thirteenth, while 7 were only twelve years of age, and one had not attained the age of seven. In most of the cases the immediate cause for the act remains a secret, but it is supposed to have been due to exceptional severity on the part of servants or teachers.

Pilocarpin in Dryness of the Tongue.—Extreme dryness of the tongue is, under any circumstances, a very distressing symptom, and one which does not readily yield to treatment while the concomitant cause remains in operation. The sucking of ice or sipping of bland fluids gives but temporary and inadequate relief, and the same may be said of glycerine employed as a paint. In this condition Dr. Blackman has successfully used pilocarpin, one-twentieth to one-tenth grain, in the form of a gelatine lamel allowed to dissolve on the tongue previously moistened with a sip of water. This small dose quickly establishes a moderate flow of saliva which persists for at least twenty-four hours, and is unaccompanied by excessive perspiration. The altered state of the mouth is often described by the patient as being delightful. Due caution in the use of so potent a remedy is advised.—*British Medical Journal.*

The New Grippe.—A doctor at Montmartre announces the second official visit of la grippe, with colors flying. Several modern improvements have been added, making it quite superior to the well-remembered plague of last year. The chief feature of the new visitation is to be a tremendous swelling of the tongue. It will fall hardest on gluttons and gossips, and will establish a suspension of their habitual operations for three days and nights. As a choice between that and the cholera, fastidious connoisseurs may choose the latter, on the principle that to act with dignity is preferable to living in ignominy for seventy-two hours, like gagged shrews of the fourteenth century.

Society Reports.

TENTH INTERNATIONAL MEDICAL CONGRESS.

Held in Berlin, August 4, 5, 6, 7, 8, *and* 9, 1890.

(Special Report for the Medical Record.)

(Continued from page 281.)

SECTION ON INTERNAL MEDICINE.

THIRD DAY, WEDNESDAY, AUGUST 6TH.

Milk Sickness.—DR. J. A. KIMMEL, of Findlay, O., read a paper descriptive of milk sickness, a peculiar disease met with in the Central Western States of the Union. The cause of the disease is not known, but it seems to prevail in parts of the country newly opened up to settlement, and to disappear from those where the soil has been brought to a high state of cultivation. Animals seem to be more liable to contract the disease when they pasture late at night or early in the morning. The affected animals usually remain immovably in one place, or wander around over a limited area slowly, and holding the head close to the ground. The appetite disappears, and obstinate constipation is the rule. A little later the animals begin to tremble, and this continues for three or four days, at the end of which time they usually die, although the disease is not invariably fatal. Oxen and bulls only are affected, cows being immune as long as they give milk. The virus of the disease is apparently eliminated through the mammary glands, for the disease is contracted by men and other animals that drink the milk coming from cows in an infected herd. The symptoms of the disease in man are very constant, and the diagnosis, as a rule, is an easy matter. The first symptom is a feeling of great fatigue, a languor which the patient, no matter how active he may be by nature, is wholly unable to overcome. Following this are anorexia, nausea and vomiting, pyrosis, and obstinate constipation. Excessive thirst is a prominent symptom. There is no elevation of temperature, indeed the latter may even be subnormal, and the pulse is usually unchanged. The skin is dry, tongue moist and coated at the tip. Respiration is difficult and sighing. The thirst is intolerable, but every drop of water that is swallowed is immediately rejected. The abdomen is retracted but is not tender on pressure. Delirium is rarely observed. Little by little the prostration becomes more marked, the patient can move neither hand nor foot, even the eyelids become immovable, and finally the patient dies in coma. The duration of fatal cases is from fifteen to twenty days, as a rule, but when recovery takes place it usually does so in from five to ten days, but convalescence is apt to be very prolonged and tedious. Milk sickness is clearly distinguished from typhoid fever, malarial affections, and gastro-enteritis by the entire absence of fever. It is possible, however, to have malarial fever exist as a complication, and then, of course, pyrexia would be present. The treatment usually employed consists in the administration of quinine, alcohol, and other stimulants. The disease in man can in almost every instance be traced to the use of milk, or butter made from it, coming from a cow pasturing with other infected cattle. The pathogenic micro-organism of the disease, if such exist, has never been isolated, but Dr. Kimmel believed that the disease was of microbial origin, and that the infecting parasite was similar to that of malaria, since the disease in cattle was contracted in a manner very similar to that of malaria in man.

Isolation vs. Antisepsis.—DR. GRANCHER, of Paris, read a long communication on this subject, in which he related the experience of the physicians of the hospital for Sick Children in Paris, in regard to isolation as a means of preventing the spread of contagious disease. His conclusions were that such measures of isolation were for the most part unnecessary. The speaker was of the firm conviction that contagion occurred usually through the medium of instruments, hands of the attendants, etc., and that the atmosphere played but a very secondary rôle in this respect. According to this theory contagion can best be prevented by strict antisepsis, and the author related a number of instances in which patients affected with some non-infectious disease were kept in the same wards with others suffering from measles and diphtheria, and did not acquire the disease.

Acute Obstructive Diseases of the Lungs.—DR. ANDREW H. SMITH, of New York, read a paper entitled "Some Considerations in Regard to Acute Obstructive Diseases of the Lungs," of which the following is a recapitulation:

1. In acute pulmonary obstruction, the danger being from exhaustion of the *right* heart, the pulse at the wrist does not give reliable indications as to the gravity of the condition.

2. This can be appreciated more correctly by studying the pulmonary circulation by the aid of the pulmonary valve-sound.

3. Marked accentuation of the pulmonary valve-sound indicates a fairly vigorous right heart, laboring to overcome resistance in the pulmonary circulation.

4. Decrease of a previously existing accentuation, with only moderate dyspnœa, indicates decrease of the pulmonary obstruction.

5. Decrease of accentuation with increase of respiratory distress indicates that the right heart is becoming exhausted.

6. Relief is to be sought (*a*) by regulating the diet in conformity with the diminished power of digestion and sanguification; (*b*) by the use of medicines which dilate the arteries and promote a transfer of blood to them from the veins; (*c*) by the inhalation of oxygen gas; (*d*) by artificial respiration; (*e*) in an emergency, by placing ligatures about the extremities in order to retain the blood in them and prevent its return to the heart.

Dr. Smith dwelt at some length upon the necessity of restricting the diet within the limit of what can be fully acted upon by the digestion on the one hand, and the process of hæmatosis on the other; both functions being impaired, the one by the general venous congestion affecting the digestive organs, and the other by the imperfect action of the respiration upon the nutritive material taken into the blood. The circulation of unassimilated material in the blood not only adds nothing to the nutrition and strength of the patient, but is a clog and hindrance to all the vital processes.

The special value of alcohol in this condition lies partly in its being an easily oxidized, and therefore an easily assimilated food, and partly in its action as a vaso-dilater.

The use of this latter class of remedies is recommended not only on theoretical grounds, but from actual experience as to their value.

Chyluria.—DR. WILLIAM H. MYERS, of Fort Wayne, Ind., read a paper on non-tropical and non-parasitic chyluria, and reported a case which he had observed. Dr. Depouser, of South Carolina, had recently reported twenty-eight similar cases, and the question arose whether this disease were perhaps advancing from tropical countries to more northern latitudes.

DR. GRAINGER STEWART, of Edinburgh, had seen a case with Dr. Buchanan, of Glasgow, which was precisely like that reported by Dr. Myers. The secretion resembled milk so closely that a cat went up to the vessel containing it and started to drink it.

FOURTH DAY, THURSDAY, AUGUST 7TH.

Treatment of Diabetes.—DR. F. W. PAVY, of London, opened the discussion on this subject. The first point to be considered was the true nature of the disease. It consists in a certain deviation from health, whereby the carbohydrate principles are not consumed and utilized in the system, but remain as carbohydrates, and are

eliminated as such. The sugar is not formed in the kidneys, but exists already in the blood. That is to say, diabetes mellitus is the expression of a coexistent glycohæmia. This glycohæmia is due to the fact that the sugar enters into the circulation under a form which it ought not to have, so that it cannot be removed from the blood during the passage of the latter through the liver. The danger in diabetes does not lie in the fact that a material which ought to be turned to account in the system runs to waste; if that were all, there would be no reason why as much sugar and starch as the individual might want should not be injected and then allowed to run off. What in reality inflicts the harm is the altered constitution of the blood, occasioned by the presence in it of the sugar which passes through the system to be excreted with the urine. In proportion to the largeness of the amount of sugar thus traversing the system in the blood, so will be the extent of deviation from the natural state, and so, in consequence, the impairment of health that will be found to exist.

The class of cases to which these remarks apply is that in which the discharge of sugar is susceptible of control by treatment, and the class embraces the majority of the cases in which the disease sets in after the middle period of life. In such instances, starting with the ingestion of carbohydrate, there follows, briefly summarized, as a consequence of the want of proper transformative or assimilative power within the system, an accumulation of sugar in the blood, attended with its discharge by the urine. Accumulation of sugar in the blood leads to the production of symptoms proportionate in severity to the deviation from the natural state. The plain object before us is to reduce this deviation as far as is found to be possible.

As long as the passage of sugar through the system is prevented no harm takes place. In the course of all his experience in diabetes Dr. Pavy had never known anything serious to arise as a part of the disease so long as the urine was kept free from sugar. There is nothing, in fact, to form the source of trouble, seeing that there is not the abnormal presence of sugar in the circulation to occasion deviation from the healthy state. On the other hand, when sugar is passing through the system, not only are there to be observed the symptoms ordinarily consequent thereon, but a constant state of insecurity exists, from the danger of the supervention of the serious issues known to follow upon the disease. Moreover, with the unnatural state occasioned by the presence of sugar, nutritive action is not carried on in such a manner as to properly maintain the strength. As a consequence, the general power becomes sapped or prematurely exhausted, and the system weakened and rendered less able to resist the effect of pernicious influences. Such is not the position when sugar is not similarly traversing the system. Indeed there is nothing then to render the state essentially different from that ordinarily existing.

The first consideration in the treatment is to control by dietetic measures the passage of sugar through the system. The real point, however, to be aimed at, is to restore the assimilative power over the carbohydrate elements of food, and until this has been accomplished it cannot be said that a cure has been effected, but only that the disease is held in subjection and prevented temporarily from leading on to an unfavorable issue. What most conduces to this desired restoration of assimilative power is the maintenance of a normal state of the system by keeping it free from the passage of sugar through it, and in this way bringing a healthy condition of body to bear in helping to promote a removal of the faulty state.

The medicinal agents which are able to effect most in the way of an actual cure of the disease are opium and its derivatives, morphine and codeine.

The influence of these agents may be witnessed in cases where the sugar has been brought down by diet to a certain point, but cannot be entirely removed from the system by dietetic treatment alone. Complete removal may then sometimes be observed to follow the subsequent administration of the drug, showing that the medicinal agent has acted in the direction of exerting a restraining influence over the abnormal production and elimination of sugar.

When it is found that the assimilative power has been restored in any given case it is permissible to consider that an actual cure has been effected; but it is always requisite to bear in mind that a weak point has existed, and it is advisable to avoid unduly taxing a power which has previously given evidence of being at fault by allowing the patient to resume the ingestion of unlimited quantities of starchy and saccharine food.

Dr. Dujardin-Beaumetz, of Paris, was unable to be present, but sent his paper, which was read by a member of the Section. He would not discuss the entire question of the treatment of glycosuria, but would confine his remarks to the consideration of the new remedies which had been proposed for the relief of this disease. In the matter of diet, he would not insist too strongly upon the entire withdrawal of bread, but would allow a little crust to those who felt the deprivation very keenly. He had proposed to substitute potatoes for bread, but this could not always be done with benefit. He thought that fruits and milk were injurious, and he would forbid their use entirely, for he had always observed that the amount of sugar in the urine increased at once after the patient began to drink any milk. Alcohol should also be forbidden, and beer should be taken with great caution. On the other hand, tea, coffee, matē, and the preparations of kola-nut exerted a favorable influence upon the course of the disease, and might be allowed freely. He favored the employment of saccharine, and believed that it could be substituted for the glycerine usually given, with benefit to the patient. But diet alone is not sufficient, and we ought to prescribe certain exercises for our patients, though it ought to be remembered that these exercises must never be taken to the point of fatigue. Amateur gardening was an excellent form of exercise, and for a woman ordinary house-work was often sufficient. Alkaline carbonated waters are often of the greatest utility. The author was in the habit of prescribing five grains of carbonate of lithium and two drops of Fowler's solution in a glass of Vichy water before each meal. The medicinal therapeutics of the disease had recently been enriched by the addition of all the new antipyretic analgesics, at the head of which he would place antipyrine, although identical effects could be obtained by the administration of phenacetine, acetanilide, and exalgine. Antipyrine should be prescribed in daily doses of from thirty to sixty grains. He would not insist upon the maintenance of a strict diet after the sugar had disappeared from the urine, but would then allow potatoes, bread, and fruits in moderation.

Dr. Seegen, of Vienna, said that it was necessary to distinguish two forms of diabetes mellitus, one in which sugar appears in the urine only after the ingestion of saccharine and starchy food, the other in which the elimination of sugar is entirely independent of the kind of food consumed by the patient. In the first case the sugar is the result of the transformation of the materials taken into the system, the liver having lost the power of converting them into glycogen; in the second it depends upon the fact that the tissues have lost their power of decomposing the sugar contained in the blood. The first variety is compatible with a long life, while the second is rapidly fatal. We do not as yet know why in one form the cells of the liver, in the other the cells of the tissues, have lost their power of dealing with the sugar contained in the blood. Fatty and albuminous foods alone should be allowed to the diabetic, although it is sometimes permissible to give green vegetables, fruits, and a couple of ounces of bread a day. Wine in moderation, may be taken, and also a little beer. When a person suffering from diabetes has received a traumatism of any kind, or when he is to undergo a surgical operation, he should be restricted to a purely meat diet. The speaker did not believe in a permanent cure of the disease and thought that a person once diabetic should always observe the

greatest caution in the matter of diet. Arsenical waters and a residence in warm countries were often of great service. In the second variety of the disease the suppression of saccharine foods tended to diminish the excretion of sugar, but it could never prevent it entirely, and it was hardly worth while to impose a strict diet of this kind upon one for whom it could be of so little service.

Dr. Cantani, of Naples, said that he had obtained a number of real cures of glycosuria, the reason for which was probably that, in Italy, diabetes was very often of alimentary origin, and this form was much more amenable to treatment than that resulting from nervous influences. He was accustomed to give fats in abundance, together with meat, eggs, and fish, but did not allow the use of milk.

Dr. Lépine, of Lyons, recalled the results of experiments showing the absence of the glycolythic ferment in animals from whom the pancreas had been removed. Undoubtedly many cases of diabetes in man depend upon a hyperproduction of sugar, but even in those he thought that much good might be expected from the absorption of the sugar ferment, if this could be brought about.

Etiology of Diabetes Mellitus.—Drs. De Renzi and Enrico Reale, of Naples, presented a joint communication, of which the following were the conclusions: 1. Diabetes may be produced experimentally by the extirpation of various organs, which, mentioned in the order of their importance, are the pancreas, the duodenum, and the salivary glands. 2. Glycosuria is produced in animals after total extirpation of the pancreas in seventy-five per cent. of the cases. 3. Clinical observation has shown that very grave diabetic symptoms follow the suppression of the salivary secretion, and the authors' experiments were confirmatory of these observations. 4. It is very probable that there exists in the organism a ferment occurring in varying amounts in the different organs, which ferment destroys sugar. 5. The treatment of diabetes should be chiefly dietetic, the best diet consisting of green vegetables and meat in proper proportions.

Dr. Minkowski, of Strassburg, said that the experiments conducted by Dr. v. Mering and himself went to prove that many cases of diabetes arise from disease of the pancreas. It is upon the extent to which this organ is affected that the gravity of the glycosuria depends.

Fifth Day, Friday, August 8th.

Myxœdema.—Dr. Ord, of London, was appointed to open the discussion of the subject. He said that, in a previous communication, Sir William Gull had made the assertion that myxœdema was a special disease of women, but the author's studies has shown the incorrectness of this. Among the cases collected by him at least ten per cent. had occurred in men. Several of the cases seemed to be hereditary in their nature. The symptoms were somewhat inconstant and are often observed to vary from one time to the other. The swelling of the skin, the speech, and especially the nervous symptoms are liable to very great and striking variations, and it is on this account necessary to study a given case with particular care in order to arrive at a correct diagnosis. Thus, in a certain number of cases the appearance of myxœdema is preceded by hypertrophy of the thyroid body, which, however, will be found to have disappeared at the time that the patient comes under observation. The author had seen one case in which the first signs of the disease were complicated with the symptoms of exophthalmic goitre. A marked tendency to hemorrhages constitutes one of the great dangers of the disease. The anatomical lesions may be divided into two groups, viz., the alterations in the thyroid body and those of other organs. In all cases, whatever the other lesions may be, the structure of the gland itself is wholly destroyed. As to the changes in the other organs, the author believed that there was a connective-tissue hyperplasia not only on the skin, but also in all parts of the body, which hyperplasia modified profoundly the structure, and consequently the function of the different organs.

Origin of the Term Myxœdema.—The speaker said that he had given the name myxœdema to this disease for two reasons: First, because the thickening of the skin is elastic and does not pit on pressure, and secondly, because in the first case that he had had the opportunity to examine post mortem he had found a large excess of mucin in the tissues. Further examinations had not, it was true, confirmed his early belief that the presence of large quantities of mucin was always to be noted, for it had been found that this depended much upon the stage of the disease as well as upon other causes. The author then referred to the experiments of Horsley, made to determine the consequence of removal of the thyroid gland in animals. These experiments would seem to show that symptoms identical with, or at least very analogous to, those of myxœdema followed the extirpation of this gland in animals, and especially in monkeys. The subsequent progress of the induced disease was dependent to a great extent upon the condition of the surrounding atmosphere, heat retarding and cold hastening the development of the symptoms of myxœdema. Dr. Felix Semon has shown that the special condition noted after extirpation of the thyroid gland, and described in Switzerland under the name of cachexia strumipriva, is identical with myxœdema, and might with propriety be called operative myxœdema. Sporadic cretinism is the same disease as myxœdema, but while the latter affects adults, the former attacks only infants, or may indeed be congenital. In these children a stunted growth, both mental and physical, is superadded to the ordinary symptoms of myxœdema. Analogous relations also exist probably between endemic cretinism and lesions of the thyroid gland. In all cases the first cause of the symptoms seems to be the loss of function in the thyroid body. In concluding, the author referred to the efforts which had been made to cure the disease by means of medicinal remedies and change of climate, and spoke especially of the recent experiments in transplanting portions of the thyroid body from the lower animals, believing that there was much to hope for in this direction, though it was too early as yet to express any decided opinion as to the real value of this procedure.

Dr. Mosler, of Greifswalde, said that the first speaker had so thoroughly covered the ground with his excellent thesis that there remained very little to be said on the subject. Extirpation of the thyroid body had one of two consequences, either an acute one (tetanus) or a chronic one (myxœdema). In certain cases in which these signs do not appear, there is either an accessory thyroid body or else the entire gland has not been removed. It is not, however, the diminution of the size of the gland that determines the peculiar symptoms, but rather the injury to the function of the organ. Progressive induration of the glandular tissue gives rise to chronic myxœdema. He then exhibited a photograph of a woman, fifty-six years of age, suffering from myxœdema. It was the perfect picture of an idiot, with an apathetic look, and with eyelids swollen and half-closed. On the face, neck, trunk, and extremities, and even on some portions of the mucous membrane were seen the characteristic swellings which have to the touch the consistence of gelatine, and are due to the formation of mucin in the subcutaneous connective tissue. The patient was now beginning to have much trouble in walking. Dr. Mosler also showed for comparison a photograph of the same person which was taken only ten years previously. There was not one feature in common in the two pictures.

Dr. Leube, of Erlangen, had observed a case of a woman from whom the thyroid had been removed, in whom, besides the ordinary symptoms of myxœdema, there was an unusual scaliness of the skin, recalling the appearance presented by ichthyosis. This peculiar change in the skin passed away in the course of a few months.

Dr. Grainger Stewart, of Glasgow, had seen one case of myxœdema complicated with mitral stenosis. This patient had a constant itching, and there seemed to be an actual improvement in the disease following the scratching which he was driven to keep up without intermission.

Dr. Gerhardt, of Berlin, had seen three cases in each of which there was a cold feeling, and relief to many of the symptoms was obtained by warm applications. The symptoms of iodism, so called, often arise, not from the action of iodine but from the rapid action of that drug upon the thyroid gland. That this is so is shown by the fact that the identical symptoms are often observed in pa tients in whom a rapid decrease in the size of the thyroid gland has been obtained by parenchymatous injections of alcohol into the gland. When the thyroid is rapidly destroyed tetanus is apt to occur, and when its disappearance is more gradual myxœdema is the result.

Dr. Baeumler, of Freiburg, said that he often saw cases of hypertrophy of the thyroid gland in the region where he practised, but he had never seen any of the symptoms of myxœdema in these individuals. In Southwestern Germany cases of myxœdema are not seen, yet it is not uncommon to meet with cretinoid persons in whom there are to be seen swellings on the skin of the face recalling the appearance presented by true myxœdema. He had recently seen a young girl in whom the entire thyroid gland had been extirpated. She developed tetanus, and died of purulent pericarditis.

Dr. A. Hanau, of Zurich, had examined the thyroid body in three cases of adult cretins. There was a conjunctive hyperplasia with glandular atrophy. The interlobular tissue was thickened, and so was the tunica externa of the arteries. The glandular atrophy was manifested by a disappearance of the epithelium in certain of the vesicles which no longer contained any of the colloid matter; in others there was a pavement layer resembling endothelium; in others only leucocytes were found; in others again, only a few atrophied cells. In all, however, some normal vesicles were found, even in those which seemed to be entirely transformed into connective tissue.

Cretinism and Myxœdema.—In comparing cretinism with myxœdema, pathologically, Dr. Hanau said there were but two points of difference to be noted, namely, that in the latter the process is much more rapid, as is shown by the abundance of leucocytes, and that in it also the epithelium disappears wholly. From a study of the lesions in the thyroid one is led to believe that cretinism is a result of the suppression of the functions of the thyroid body, in this respect being closely related to both spontaneous and operative myxœdema. The clinical differences between the three conditions seem to depend upon the age of the patient, and the mode of destruction of the gland, which is immediate in operative cases, rapid in myxœdema, and slow in cretinism, and upon the fact that the destruction of the gland is total in myxœdema and only partial in cretinism. The latter fact explains why cretins often live for a long time, while those suffering from myxœdema die within a comparatively short period.

Dr. Ewald, of Berlin, had observed a case in the Augusta Hospital which during life was supposed to be suffering from myxœdema. After death, which occurred rapidly, nothing was found except an enlargement of the thyroid gland, which was found on microscopical examination to present the lesions of inflammatory swelling and alveolar degeneration. The author thought that we still had much to learn concerning the nature and cause of myxœdema.

Dr. Fletcher had made eight autopsies on cases of myxœdema, in all of which he had found a large amount of mucin in the blood.

Treatment of Anæmia.—Dr. Laache, of Christiania, opened the discussion on this point, in which he said that the sole indication for the administration of iron was the existence of true primary chlorosis. The continued employment of preparations of iron is not advisable, and yet relapses are very common as soon as the use of this drug is discontinued. It is very possible that the vascular changes noted by Virchow may have much to do with the occurrence of these frequent relapses. Arsenic gives good results in cases of progressive pernicious anæmia, but here, too, relapses are not uncommon. It is also necessary, before passing final judgment on the value of any remedy in this disease, to remember that spontaneous recoveries sometimes take place. For this same reason it is always well to be guarded in the prognosis of a case of anæmia, even though it be of extreme severity and accompanied by frequent fainting spells. The mode of action of arsenic is as little understood as is that of iron. We know, however, that in the cases in which iron is useful (chlorosis), the hæmoglobin is reduced in amount both relatively and absolutely, that is to say, the globules are reduced in number and are also pale in color. In cases of pernicious anæmia, however, in which iron is of no service, the hæmoglobin is only reduced in so far as the number of red blood-corpuscles is less, the corpuscles themselves being of normal color and containing the correct proportion of this principle. It would seem, therefore, that the iron acts in a special manner upon the hæmoglobin. In certain cases, the so-called fecal anæmia, purgatives are of undoubted service. This form of the disease is probably due to a chronic poisoning by the fecal matter remaining in the intestine. As to the utility of inhalations of oxygen, authorities are not at all agreed. In pernicious anæmia, or in that form which remains after exhausting hemorrhages, transfusion is often of real service.

St. Gothard Tunnel Disease.—Dr. Bozzolo, of Turin, said that he had seen a great number of cases of St. Gothard anæmia, caused by the presence of the ankylostomum duodenale. This form differs somewhat from other varieties of pernicious anæmia, among other respects by the complete absence of retinal hemorrhages. For the cure of this disease Perroncito had employed the extract of male fern with success. The speaker had had good results with thymol given in doses of two or three drachms a day. Most of the patients so treated recovered rapidly after the evacuation of large numbers of the parasites.

Treatment of Diphtheria in America.—Dr. A. Jacobi, of New York, read a paper on the "American Therapeutics of Diphtheria," in which he outlined the methods most favored by authorities in this country. Special attention, he said, was paid to prophylactic measures. He referred to the use of chlorate of potassium and tincture of iron, and then mentioned the remedies most commonly employed in the local treatment of the throat. Gargles were useful at times, but they were being very generally supplanted by nasal injections. Alcohol should be freely given, and its administration should be begun early, so as to anticipate the ever-threatening heart failure.

The author spoke of the effects of mercury on this disease, and then alluded to the operative treatment by intubation, which had in a measure supplanted tracheotomy because of the rapidity, bloodlessness, and efficiency with which it can be performed. In every case, isolation is enforced, fluid food given, moderate stimulation resorted to, and absolute rest enjoined, even the nasal injections being made with the patient in a recumbent or semi-recumbent posture.

Pseudo-Microbes in Human Blood.—Dr. Kollmann, of Leipsic, read a paper in which he reported having observed in normal blood, obtained under the strictest antiseptic precautions, a number of small bodies, some of which were barely visible as minute points, others of a round or elongated shape and about one-half of a micromillimetre in diameter. Others again had the form of cocci, diplococci, streptococci, bacilli, etc., and had very active movements. They were without doubt the remains of the red blood-corpuscles or of the disintegrating white globules. Examination with staining agents, as

well as culture experiments, showed clearly enough that they were not micro-organisms. The speaker thought it not improbable that the supposed malaria bacillus of Tommasi-Crudeli and others were of similar origin.

Dr. Tito Gualdi, of Rome, said that some of the bodies described by Klebs and Tommasi-Crudeli were undoubtedly of artificial origin, but there was also no doubt of the existence of a malarial plasmodium, which is found nowhere else than in the blood of patients suffering from malaria. It is impossible at the present day for anyone with even a very moderate experience to confound these two forms, which are totally distinct the one from the other.

Sixth Day, Saturday, August 9th.

Splenotyphus.—Dr. Eiselt, of Prague, read a paper with this title, in which he described a form of typhoid fever where the mass of the infective material was found in the spleen rather than in the intestine. The author distinguished three clinical forms of the disease. All the varieties, however, are clearly marked off from the intestinal form of typhoid by the entire absence of intestinal symptoms, by the presence of an enlarged spleen, and by a peculiar temperature curve.

First form: Large splenic tumor, with adhesive or exudative perisplenitis, either confined to this region or spreading to other portions of the peritoneum.

Second form: A rapidly enlarging spleen, often attaining an enormous size, not infrequently caused by hemorrhages within the organ. There is a continuous fever of considerable intensity, lasting from six to seven weeks, and not infrequently returning after a week or two of apyrexia, and then remaining as long as the spleen continues enlarged.

Third form: Spleen considerably enlarged, with a high fever which assumes a relapsing or intermittent form, coming and going at intervals of about a week, but never accompanied by the presence of spirilla in the blood.

The true typhoid nature of this disease is shown by the fact of infection, and by the discovery at autopsy of a few isolated ulcers in the ileum.

Treatment of Chronic Diarrhœa.—Dr. Eccles, of London, presented a communication on this subject, in which he recommended absolute repose, a restricted diet, the maintenance of an equable temperature in the patient's dwelling, and the employment of massage. He also spoke highly of the action of salol, which he was in the habit of giving in moderately large doses. Under the action of this remedy the stools diminish in number and become more consistent.

Treatment of Dysentery.—Dr. v. Schroeders, of Valparaiso, read a paper on this subject in which he held that the treatment of dysentery with large doses of ipecac was as certain in its effects as the treatment of malaria with quinine. The most severe cases of dysentery can with certainty be cured by this means, and even the various complications can also be cut short. The patient should be kept during the day on a rather restricted fluid diet, and in the evening should receive from one-half to one grain of opium. When he has begun to come under the influence of this drug, as shown by drowsiness, the ipecac should be given in capsules in the dose of from thirty to sixty grains, very little water being allowed with it. The good effects of the remedy are seen immediately, and the following day the patient is found to be nearly well. If vomiting should have occurred, the same process ought to be repeated on the following evening. If there is still some mucus in the stools, an injection may be given of from sixty to ninety grains of ipecac in a pint of water. This mode of treatment is the ordinary one in use in South America, and has superseded all other remedies. The speaker related the case of a lady who had suffered from dysentery during a voyage from Valparaiso to Hamburg and return, and who was cured definitely by a single dose of ipecacuanha.

Diagnosis of Abscess of the Liver.—Dr. Pel, of Amsterdam, presented a communication in which he laid down certain rules to assist in the diagnosis of this condition. In arriving at a diagnosis we must consider the objective and subjective symptoms and the etiology. Among the objective signs to be taken into account are the fever and the enlargement of the liver. The subjective symptoms are pain in the region of the liver and in the right shoulder, mental depression, anorexia, insomnia, and emaciation. A determination of the cause is of great moment; among the etiological factors are a residence in the tropics, gall stones, typhoid fever, traumatism, echinococcus cysts, and dysentery. Not uncommonly, however, it is impossible to discover any cause for the abscess in cases where a residence in tropical regions can be excluded. There are, furthermore, some cases of abscess of the liver, centrally situated and small in extent, in which the symptoms are so obscure that it is not possible to make a diagnosis.

BRITISH MEDICAL ASSOCIATION.

Fifty-eighth Annual Meeting, held at Birmingham, England, July 29, 30, 31, and August 1, 1890.

(From our Special Correspondent.)

(Continued from page 284.)

SECTION IN SURGERY.

Second Day, Thursday, July 31st.

Operative Treatment of Acute Intestinal Obstruction Due to Internal Strangulation.—Mr. Greig Smith, of Clifton, read a paper on this subject. He remarked that to surgery alone could we look for a cure in these cases. Valuable time was often wasted in the administration of drugs. There were many elements to be considered in acute obstruction: The mechanical constriction of the bowel might be caused by the kink of a portion of gut sharply bent upon itself (illustrated by a soft elastic tube); the general state of the patient and his ability to bear operation; the condition of the intestinal tract, and other points, the neglect of which in any particular might cause the death of the patient as surely as if he were left alone. Every detail of the schools must give way to the prime object of saving human life. What we wanted was physiological rather than anatomical surgery. The medical and physiological surgeon might not be dainty in his operations; but, on the other hand, the proceedings of the rigid anatomist often resembled those of the post-mortem room. The degree of virulence of obstruction must be considered; its duration was a probable, but not a safe guide, and the same might be said of sensibility. The character of the vomiting was not of great importance. It was certainly wrong to make fecal vomiting a plea for operation, and *vice versa*. Suppose percussion showed no dulness and there was little or no tenderness. Before operation a nutrient enema should be administered. The incision should extend for two inches below the umbilicus. Inspection enabled the operator to fix on the most likely piece of gut, and by following this up, as a rule, he arrived at the point of obstruction. Special operative procedures he did not purpose to discuss. In an ideal operation the vital powers of the patient would not be exhausted. In a second imaginary case, after a week or more of obstruction, the patient's strength was waning. Fluid was gradually replacing gas inside the elastic tubes. The stomach was getting exhausted. The distended coils of bowel were visible through the abdominal wall. Here the struggling under anæsthesia would be full of risk. He would wash the stomach out and give chloroform only long enough to allow of the abdominal incision and the fixing of sutures. The rest of the operation could be done painlessly. In the worst cases, where the patient could not stand an anæsthetic, he would trust to local anæsthesia, as cocaine. After removal of obstruction the gut is left paralyzed. Mechanical obstruction occurred

every few inches from the kinks at its numerous flexures; to remove this, intestinal evacuation and drainage were necessary, the surgeon remaining at the bedside several hours, if necessary, for this purpose. The bowel being punctured with a hollow needle, at first there would be free flow of fluid; this continued until the abdomen was quite flat. The bowel was then closed with a continuous suture, and returned, it being unnecessary to fasten it to the skin. It was wiser to perform enterostomy than to make a prolonged search. Enterostomy or intestinal drainage would often save life, even in apparently hopeless cases. The bowel might be caught and fixed with quilled sutures and drained. No operation required more rapidity of thought and action on the part of the surgeon.

MR. MAYO ROBSON, of Leeds, quite agreed that we ought never to go to a case of the kind with preconceived notions. He had had personal experience of fifty cases, but, speaking generally, he thought statistics were not of much good. Treves said that forty per cent. of lives are saved, but he felt perfectly certain that if all cases of operation for acute obstruction were reported, the percentage would be much less. To wait was as great an error as delay in dealing with strangulated hernia. The more he saw the more certain he felt that it was often utterly impossible to diagnose. He had a rude shock of this kind in the case of a lady who felt sudden pain in the abdomen after a strain, followed by vomiting and all the symptoms of intestinal obstruction. On opening the abdomen he found a cancer of the transverse mesocolon, which must have been there for some time. It had been proposed after finding cancer to turn the patient over and perform a lumbar colotomy. This course he objected to, as it involved a long and tedious double operation. He had opened the abdomen under cocaine in a patient of seventy. No pain was felt, the obstruction was removed, and the patient recovered. Under an anæsthetic she would have died. In one case, where patient could not stand a prolonged search, he pushed in a large trocar. Where the whole of the bowel had been turned out, recovery rarely takes place. He predicted great future success in these operations. If operation be done early there was plenty of time to explore. If called in, say about the tenth day, all that could be undertaken was a very modified operation under local anæsthesia. Unfortunately, laparotomy was looked on too often as a last resort. The surgeon should learn to say "No" to the temptation to explore every abdomen when laid open. His aim should be to attempt relief first and cure afterward. Tapping through the belly-wall did not need notice. Opium undoubtedly relieved the pain, but lulled both patient and surgeon into a position of false security. Bell wished opium had never been known.

MR. KENDAL FRANKS, of Dublin, said that the operation was practically on the same ground as that for strangulated hernia, and the day of drugs was gone. Most hospital surgeons now preferred the knife to taxis. There was no particular reason why intussusception should always be the fatal operation it now was, any more than in strangulated hernia.

MR. BENNETT MAY, of Birmingham, said if we could diagnose beforehand the state of matters inside the belly the task of the surgeon would be simplified. After operations he had often seen the necessity of an operation, if it could have been undertaken without killing the patient. Primary enterotomy he regarded as a retrograde proceeding, except, of course, where it was the only resource; such as cancer of rectum. In operations for internal strangulation results had been appalling. He advocated free incision to admit four fingers, or hand, as an economy of time. He would then pass his hand to the bottom of the pelvis and search for the collapsed coil. When distended bowel could not be reduced, he opened the gut, emptied it, and sewed it up. In obstruction due to peritonitis this proceeding was unnecessary. In his experience the median line was unfavorable for opening the abdomen. The important question was, what the patient would stand.

MR. W. D. SPANTON, of Hanley, forwarded a communication, which was read, in which he stated that he had known cases coming on at menstrual period; it would be interesting to know the experience of other surgeons on this point.

MR. F. MARSH, of Birmingham, looked on all these cases as practically strangulated hernia. He advised operation the moment there was even a suspicion of obstruction. The change that took place in the patient's condition was rapid. An important point was the cooling of the patient's breath in collapse. He advocated free incision, at least three inches long, for one reason because coils of gut were often adherent to the peritoneum. If he could not find the cause of obstruction after a rapid search, he would perform enterostomy.

MR. BOWREMAN JESSETT, of London, regretted that Senn and Hutchinson were not present, as their methods were so opposite. He made a great point of preliminary treatment by injections and by washing out stomach, especially in fecal vomiting. The latter proceeding also prevented sickness during and after operation. Where patient was greatly collapsed he would make a small opening into abdomen and perform enterostomy. He had done numerous successful experiments on dogs with Senn's plates. He would begin with a small incision of two inches, to be enlarged if necessary. In opening gut he would incise and not puncture, as the latter would remain open. He related a number of operative procedures, such as implanting the ileum into the transverse colon, and many others, performed with the aid of Senn's plates.

MR. BUTLIN, of London, said there could be no comparison between the operation for ordinary intestinal obstruction and herniotomy. In the latter the operation was done early, and was soon over, while the bowel was sound and the results good. Things were exactly opposite in obstruction. The surgeon was sent for commonly as a last resource when drugs had failed. He was opposed to the teaching that it was right to open the abdomen in cases of the least doubt. Such questions of detail as the preparation of patient had been settled for years. At present abdominal surgery was a list of horrors. He himself had had one successful case, operated on the same day as admitted, so that his percentage of recoveries was probably higher than that of many other surgeons.

MR. BARLING, of Birmingham, said that the absence of disastrous records simply meant there was no operation. Inquiry often elicited a history of small intestinal troubles extending over a long period. It should be remembered that we were dealing with atrophied and dilated bowel that could not help itself.

MR. GREIG SMITH, in closing the discussion, said he had not gone into such details as preliminary preparation of patient because they were not germane to his paper. As a matter of fact he at once stopped all food and all medicines by the mouth. His operative measures included intestinal drainage, intestinal evacuation, and enterostomy. Out of thirty-five cases he had saved ten, figures on which he hoped to improve. Mr. Butlin had taken up the strong ground that he would always refuse to operate. He himself would refuse no operation. He made an incision into the bowel and drained it, keeping in brandy (two ounces) every two hours. The incision should not be too long, and as near the obstruction as possible. Affected bowel would be full of fluid and low down. Any clear gut presenting he would push aside, and, looking for darker gut, follow it down; tense mesentery was a valuable guide. The surgeon wanted constant practice in the post-mortem room. Groping about with four fingers he condemned.

Operation in Fracture Involving the Articulations.—MR. WATSON CHEYNE, of London, read a paper illustrating the importance of operation in complex fractures of joint. Where there was stiffness or displacement, with

loose fragments or extensive comminution of joint, it was better to operate at once and remove or fix the fragments. He did not for a moment advocate cutting into all joints which were involved in fractures, but he wished to show what might be done under some difficult circumstances. He narrated the details of four cases. In one there was a fractured hip. The patient had suffered from infantile paralysis on the other side, so that bony union of the fracture was of importance. As a further complication, she suffered from acute bronchitis, and was unable to lie in bed. The operator accordingly cut down on the fracture, which was partly extra- and partly intra-capsular, and brought together the fragments with ivory pegs passed through the trochanter and head of femur. No drainage-tube was used, and the limb was put up in plaster, with the result of firm union and slight shortening. In another case a boy injured his elbow. On laying open the joint extensive injuries were visible—smashed coracoid, olecranon, and external condyle. The olecranon was wired, and the other parts removed, with good result of a fair amount of movement. Of the two remaining cases, one was fracture of an old dislocated patella, causing stiff knee, which was operated on successfully.

Mr. Kendal Franks, of Dublin, read a paper on the use of massage in recent fractures and dislocations. By emptying serous channels and relieving congestion he claimed that, if applied early, massage would prevent stiffness and adhesions in many fractures. A true economy of time was effected in this way, shortening the period of recovery by one-half. The speaker entered minutely into the physiology of the action. Severe sprains might be cured in from seven to ten days. The method was especially applicable to dislocations, where it removed the serous effusion that prevented the exercise of joints. Several illustrative cases were narrated.

Third Day, Friday, August 1st.

Electric Cystoscopy.—Mr. Hurry Fenwick, of London, read a paper on "The Influence of Electric Illumination of the Bladder upon Our Knowledge and Treatment of Urinary Diseases." He remarked that so much good and useful work had already resulted from the employment of the electric cystoscope as a means of diagnosis in the bladder that there was no necessity for him to vindicate the utility of the instrument. The following pathological preparations, procured from cases in which a diagnosis had been made during life by means of the cystoscope, would still further prove its diagnostic value. He was in the habit of making drawings and models of the condition of things, as revealed by the cystoscope, for the benefit of the general practitioners who sent him cases in consultation. He then showed five specimens of sarcomatous and carcinomatous growths of various sizes taken from the bladder, where post-mortem examination had verified the diagnosis made during life. Following these successful cases were two in which he had failed to make a correct diagnosis—one being a calculus, not revealed by the cystoscope, the other a case of polypus of the bladder, which was discovered by the cystoscope at a later period only, and after repeated examinations. He had come to the conclusion that by intelligent, patient, and dexterous use the cystoscope was of great value in diagnosis. Turning next to the use of electric illumination of the bladder in relation to kidney disease, he had found it afforded valuable indications as to what extent the kidneys respectively were in action. While watching the ureteral orifices much information could be gained respecting the condition of the kidney by noting the rapidity of the flow and the color of the fluid coming from them. Even the density of the fluid could be gauged to a certain extent by noticing the fusion circles produced at the ureteral orifices. Minor points, such as the condition of proptosis of the orifice, could be made use of in diagnosing the state of affairs beyond the bladder. In one case he had been able to diagnose the presence of carcinoma of the kidney by seeing blood emerge from the ureter and coagulate almost in the act of doing so. In cases of ulcerations on the posterior wall of the bladder, with symptoms almost undistinguishable from stone, he had been able to make a definite diagnosis. He had seen many such cases where the patients had been cut for stone. This form of ulceration, when not recognized and not treated, passed into the true tubercular condition, which sooner or later involved the ureters and other parts. It frequently happened that the sound did not detect the presence of stone in the bladder. That occurrence was generally due to the presence of sacculi, in which the stone was more or less encysted, or to a swollen state of the mucous membrane, in which small stones were completely embedded. In these cases, where they could not be felt by the sound, they might be actually seen by means of the cystoscope. He referred to an interesting case of this kind in his own practice, in which the bladder was kidney-shaped and a stone rested on a sort of shelf inside the viscus where it could not be felt by the sound, but where it was seen by the cystoscope. With regard to tumors of the bladder, he called attention to some common errors, among them the supposition that simple villous tumors were the most common, whereas the malignant carcinomata were undoubtedly more common than any other kind. Another error lay in the idea that hemorrhage was an earlier symptom in benign growths than in malignant, but according to his experience the reverse was the rule, hemorrhage being of very early occurrence in malignant growths. As other symptoms of the latter he mentioned alternations of comfort and extreme pain, and intermittent cystitis. The origin of vesical growth from the trigone was exceptional, its common origin being from the posterior wall just below the orifices of the ureters.

Mr. Bruce Clarke, of London, read a paper on "Obscure Bladder Affections, and Their Exact Diagnosis by the Cystoscope." He said the value of the cystoscope was greatest in cases presenting exceptional symptoms, for there a correct diagnosis could be followed by appropriate treatment. The following brief notes referred to a case that came under his care in 1887. The patient, a male aged thirty-four, six years previously contracted gonorrhœa, which yielded to ordinary treatment in fourteen days. A year later he had some hemorrhage from the bladder. This passed off and was followed two days later by cystitis with occasional hemorrhage. Both these symptoms lasted from two to fourteen days. This went on for the next five years, when he came under the author's care. The patient was then suffering from cystitis, with unusual loss of blood. On examination with the cystoscope a growth was discovered close to the neck of the bladder; this was removed by supra-pubic operation and the patient recovered completely. Notes were next given of four other obscure cases, namely: 1, Chronic cystitis; 2, epithelioma; 3, encysted calculus, with second encysted calculus after removal of the first; 4, tubercular ulceration. These were all diagnosed by means of the cystoscope, which led to more successful treatment than had before been adopted. While speaking highly of the great value of the cystoscope in cases of cystitis of uncertain origin, he admitted that examination by means of that instrument was not always successful. With regard to the supra-pubic operation, he preferred doing it in two stages, first sewing the bladder to the abdominal wall, and opening it a day or two later. As local applications he spoke highly of a solution of lactic acid, from three to ten per cent., in case of ulcers of bladder with phosphatic deposits; also of a five per cent. mixture of iodoform in mucilage in tubercular ulceration of the bladder.

Mr. Gilbert Barling, of Birmingham, remarked that patients reaped great benefit from the application of the cystoscope. Its utility depended to a great extent on the experience of the operator in its practical use. He referred to four cases in which a diagnosis of malignant

tumor had been made, and operative treatment avoided with advantage, as well as other cases which had been operated on with success. He condemned scraping and the use of evacuators to obtain portions of tumor for examination as crude methods, and detrimental to the patients. He quite agreed with Mr. Fenwick in his statements as to the utility of the instrument in aiding diagnosis of kidney conditions, and also in the recognition of tumors of the bladder at such an early period that operative measures become much more justifiable and successful. Benign growths nowhere became more rapidly malignant than in the bladder, and late operations were always extremely unfavorable. Irritation of the bladder is an early symptom of malignant growth, but hemorrhage is far more commonly a first symptom. He further deprecated the value of the microscopic examination of scrapings, inasmuch as around carcinomatous patches simple villous growths were common, and if a portion of this happened to be procured its examination could only be entirely misleading. He thought the ratio of malignant to simple growths was about four to one. Mr. Bennett May and Mr. Bartleet also joined in the discussion.

Mr. Bruce Clarke bore testimony to the frequency with which villous growths surround an epitheliomatous ulcer, "like rushes round a pond." In cases of stricture and in children he had frequently examined with the cystoscope through a perineal incision made after Whitehead's method. Reference had been made to the bladders of children. In the majority of cases he thought they were due to phosphatic deposits, and were, therefore, not tubercular. They could be readily cured by rest in bed and proper diet.

Mr. Hurry Fenwick, in closing, spoke highly of lactic acid as a wash in slowly progressing ulcers of the bladder. He thought that malignant tumors bore even a higher proportion to benign than four to one.

Operations on the Lateral Ventricles.—Mr. Mayo Robson, of Leeds, read a paper on "Tapping and Draining the Ventricles in Certain Cases of Brain Disease." Looking at the success which has attended opening and draining the abdomen in cases of chronic peritonitis, he had come to consider the question, with what degree of safety can we open the skull cavity in cases of a somewhat similar nature. Thanks to the labors of Ferrier, Goltz, and others, many cases of brain disease were capable of being accurately localized and successfully treated. In those cases of brain disease, such as meningitis, which were not so definitely localized, and which on the supervention of coma become absolutely hopeless, could we not attempt some surgical treatment with a prospect of success? We opened the abdomen and the pleura, why should we not open the skull and tap or drain the ventricles?

He quoted the following case which had come under his charge. A boy, aged ten, with symptoms of inflammatory brain mischief; he had a temperature of 103° F.; right hemiplegia and aphasia; twitching of limbs of right side of body; double optic neuritis, etc. He suspected cerebral abscess or basal meningitis, and decided to adopt surgical measures. A. C. E. mixture was administered and the cranial cavity opened with a ½-inch trephine over the motor centres on the left side. The brain was non-pulsatile, and no pus could be found. He pushed the needle into the lateral ventricle and drew off ten drachms of clear fluid. Healing went on satisfactorily and the patient showed continual improvement. Six months later he was in good health, but had some convulsive seizures of the right arm. These were relieved by bromides, and the patient is at present apparently in perfect health. Drainage could be continued over longer or shorter periods, as long as the wound was maintained perfectly aseptic. He had drained the spinal canal successfully in several cases of syringomyelocele. He entered into the details of his manner of operating, but these do not differ materially from those usually adopted in operations on the brain. He referred to a case of hydrocephalus which he had treated in a similar way, but without success.

In the discussion which followed, Mr. Bruce Clarke, of London, said he thought the removal of a large quantity of cerebro-spinal fluid a dangerous proceeding. He had drained several cases, but they had all proved fatal, and death had resulted in his opinion from the effect produced on the cerebral circulation by the removal of the fluid. He had operated on two cases of purulent basal meningitis, but he thought that, unless we could devise some means of washing out the cranial cavity, we should not meet with success in these cases. He had given up using the spray and, in fact, did not use any antiseptics at all during the operation, although he did so to the parts previous to commencing.

Mr. Kendall Frank, of Dublin, thought that, as much benefit was derived from simply incising and draining the peritoneum, the same ought to be the case in the brain. He quoted a case in which he tapped the lateral ventricle and drained it, for supposed middle-ear brain disease; the patient died on the fourth day. On making a post-mortem examination he found the ventricle almost empty, containing a little bloody serum, but there was basal tubercular meningitis.

Mr. Wheelhouse, of Leeds, spoke strongly against the practice of tapping the ventricle in chronic hydrocephalus. It had fallen to his lot to do it once in the case of a child, who after it steadily sank and died, and he certainly should never do it again. He thought the three cavities referred to were placed under totally different circumstances. After removal of fluid from the peritoneum the abdominal walls accommodate themselves to the altered condition, and the lung fills up the pleural cavity; but the brain cannot expand to fill up the deficiency left by the withdrawal of fluid, so that we cannot hope for the same success in applying the same kind of treatment to similar conditions of the brain.

Mr. Mayo Robson said that he did not mean his remarks to apply to cases of chronic hydrocephalus, but thought that the treatment was justifiable in those cases which ended in coma, and which were otherwise quite hopeless. He said there were many cases recorded in which cerebro-spinal fluid had drained without any fatal result; it was merely a question of gradual instead of sudden withdrawal. He always used antiseptics, and although he did not think the spray essential, he preferred using it in large public institutions, whereas he dispensed with it in private houses. In referring to Kendall Frank's case of tubercular meningitis, he thought that, as long as it had not reached the purulent stage, there was hope of treating it successfully by surgical proceedings; but once purulent, he could not see how the pus could be washed away.

Mr. F. Marsh, of Birmingham, brought in a cab-driver whom he had shown twelve months ago at the Leeds meeting of the Association. Shortly before that meeting he had performed Madelung's operation on him for a rectal growth, and had also excised the rectum with the growth. The anal orifice was now completely closed and soundly healed. The colotomy anus acted well, with the exception of a tendency to protrusion of the mucous membrane, for which he wore a pad. He was otherwise in perfect health and followed his usual occupation.

Zinc Sulphite in Antiseptic Surgery.—Dr. F. T. Heuston read a paper "On a Non-poisonous, Non-irritative Antiseptic Dressing." Calling attention to the poisonous and irritating nature of many of our ordinary antiseptic dressings, he spoke highly of the value of zinc sulphite ($ZnSO_3$,H_2O) as a non-poisonous and non-irritative dressing. It was used in the form of an impregnated gauze; this was tinted red with a vegetable dye. By this means it could at once be seen whether the zinc sulphite had undergone any decomposition, for on wetting it the color disappeared if the sulphite had undergone no deteriorating changes.

Mr. Kendall Frank, of Dublin, had frequently used

the zinc sulphite gauze, and was very well satisfied with it. Under its use wounds had uniformly healed by first intention.

Mr. Davies Colby, of London, described a method of closing the hard palate by a new operation. By means of diagrams he demonstrated his method of operating, which was as follows: He made his first incision from opposite the central incisor of one side, carrying it close along the margin of the hard palate to opposite the last molar tooth. Another incision, commenced from the same point as the first, passed backward one-eighth inch from the margin of the cleft to the post-margin of the hard palate. Both incisions reached the bone. This flap was raised with the periosteum and thrown backward and outward. A flap was next raised from the other side by an incision which commenced at cleft opposite central incisor the other side, was carried backward one-sixth of an inch from margin of cleft as far as last molar, curving in to cleft again. This flap was raised and its margin was sewn to the opposite margin of the cleft by two silver wire sutures. The first flap was then carried across the cleft and fixed by wire sutures.

The advantages claimed for this operation were: 1. There was less hemorrhage. 2. Not so much bruising as in old operation. 3. Nothing was cut away. 4. Absence of tension. 5. No sloughing. 6. Upward pressure of tongue was beneficial rather than otherwise. 7. The bridge was strong (mucoperiosteum). 8. It could be done much earlier (one to two years), and thus obviate much deformity.

Its disadvantages were: 1. The hard palate alone was united. 2. The foramen in fore part of cleft had to be closed later, if it did not close by itself.

The soft palate had to be closed later by a separate operation. He recommended this operation: 1. In infants. 2. Where the other had failed. 3. Where the gap was great, the sutures could be left in for from five to six weeks.

Hydatid Tumor of the Liver.—Dr. Thomas Eastes, of Folkestone, narrated a case of "Abdominal Section for Doubtful Tumor, Hydatid of Liver Found and Treated by Incision and Drainage." The tumor was at first taken to be probably of mesenteric origin; on opening abdomen it was found to be a hydatid cyst of liver. It was opened and drained with a successful result.

Operative Treatment of Cancer of the Intestinal Tract.—Mr. F. B. Jessett, of London, read a paper on "The Surgical Treatment of Carcinoma of the Pylorus and Intestines." From pressure of time very little of this important paper was read. It included a full discussion of methods of performing pylorectomy, gastro-enterostomy, enterorrhaphy, ileo-ileostomy, ileo colostomy, and other operations, chiefly by means of bone plates.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from August 31 to September 6, 1890.

Baxter, Jedediah H., Colonel and Chief Medical Purveyor. To be Surgeon-General, with the rank of Brigadier-General, August 16, 1890, vice Moore, retired from active service. Headquarters of the Army, A. G. O., Washington, September 1, 1890.

De Witt, Theodore F., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month, to take effect September 15, 1890. S. O. 76, Headquarters Department of Texas, San Antonio, Tex., September 1, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending September 6, 1890.

Wise, J. C., Surgeon. Detached from Torpedo Station and ordered to the Alliance.

Fitzsimons, Paul, Surgeon. Ordered to the Torpedo Station, Newport, R. I.

Bright, George A., Surgeon. Detached from the Constellation and ordered to the Naval Academy.

Alcott, F. W., Assistant Surgeon. Promoted to be Passed Assistant Surgeon.

Wentworth, A. R., Passed Assistant Surgeon. Requests to withdraw resignation. Granted.

Crawford, M. H., Passed Assistant Surgeon. Detached from the Monongahela and granted two months' leave of absence.

Keeney, James F., Assistant Surgeon. Detached from the Richmond and granted two months' leave of absence.

Lowndes, Charles H. T., Assistant Surgeon. Detached from the Naval Academy and ordered to the Richmond.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 6, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	42	15
Scarlet fever	15	1
Cerebro-spinal meningitis	1	1
Measles	70	7
Diphtheria	45	11
Small-pox	0	0
Varicella	2	0
Pertussis	0	0

The Process of Senescence.—At the meeting of the American Association for the Advancement of Science, held recently in Indianapolis, Dr. Minot read a paper entitled "Certain Phenomena of Growing Old," in which he stated that the curve which denotes biological changes is asymmetrical, rising very rapidly in youth and declining gradually as age advances. This form of curve is found in almost all kinds of biological changes. He has already announced his belief that the percentage of growth, which may be taken as an index of vitality, declines from the very beginning of life. The notion, then, that there is not, from a scientific point of view, any distinction to be made between development and decline is the first important point presented.

The second point of the inquiry is, how far any anatomical peculiarities in the organism can be correlated with this gradual loss of vitality. Omitting the usual senile characteristics as pertaining only to extreme old age, the paper was mostly a comparison of the youngest with the adult tissues, comprising the germ layers, outer, middle, and inner, of the embryo. The outer layer forms the external covering of the body; the middle gives rise in great part to the muscles, connective tissue, and skeletal elements, the blood and blood-vessels; the inner forms the lining of the digestive tract.

At first the cells of the outer layer have each a nucleus, and around that nucleus a small amount of protoplasm which, in the child at least, is remarkable for assuming a triangular outline. In the adult the amount of protoplasm is very greatly increased, and the form of the cell changes. This increase in amount of protoplasm relatively to that of nucleus was traced in the second group of tissues in detail, and changes of form were shown in the following order: nerve cells, striated muscles, pancreas cells, cells of thyroid and salivary glands, and of the spleen. In the inner layer also the same changes occur in proportion of protoplasm, increasing as age advances.

He concludes that, inasmuch as the progressive loss of vitality throughout life is attended by a progressive increase in the proportion of protoplasm to nucleus, there must be a relation of cause and effect between these two phenomena; in other words, "protoplasm is the physical sign of advancing decrepitude." Hitherto we have had comparative anatomy and physiology, but of general biology extremely little. Dr. Minot expressed his belief that the future of biology would lead in this direction, and that the study of the organism as a whole would supersede in the near future to a large extent the present study of the separate organs, both in their physiological and morphological aspects.

There is a great deal to be done, for it is only in the domain of general biology that we can seek the solution of the problems of reproduction, heredity, sex, growth, variation, death, the evolution of species, and the general economy of nature. All of these phenomena are common alike to the vegetable and the animal world, and for their thorough study it is necessary that the investigator should be strictly a general biologist, and not merely a botanist or zoölogist. These investigations are necessarily expensive in character, since they require that the animals and plants experimented upon be kept under specific conditions for long periods of time; but it is to be believed that the results which may be obtained will amply justify both the labor and the expense. Dr. Minot expressed the hope that some persons who felt generously inclined to aid in scientific work might give support for this line of work, and in concluding expressed the more general hope that those persons of wealth who wish to contribute to science should feel more and more inclined to endow research, for much more can be accomplished in this way than in any other for the advancement of science.

The Form of the External Ear.—According to Professor Garrison, of Chicago, the crumpled and crushed form of the human ear was originally caused, and is now maintained, by the habit of lying on the side of the head, and that this habit has principally resulted from the great and increasing weight of the brain. The question originally seemed to be whether man's ancestors would profit most by large brains or by symmetrical and perfect acoustic apparatus, and nature by selection had promptly decided in favor of large brains.

Certain Reactions for Tyrotoxicons.—Professor H. A. Weber, of Columbus, O., read a paper on this subject at the recent meeting of the American Association for the Advancement of Science. Through the Ohio State Board of Health and the Ohio State Dairy and Food Commission, the writer had, within the last few years, received numerous samples of poisonous cheese for examination. The samples were tested for tyrotoxicon according to the well-known method as published by Dr. Vaughan. About fifteen hundred grains of the cheese was cut up into small cubes, placed into a percolator, covered with distilled water, and allowed to digest at ordinary temperatures for several hours. The aqueous extract was then withdrawn and more water added, a little at a time, until about one litre of percolate was obtained. This was rendered alkaline with sodium carbonate extract with half its volume of Squibb's ether and the ether allowed to evaporate spontaneously. After complete evaporation of the ether, the aqueous solution was subjected to the following tests:

One drop was added to a mixture of ferric chloride and potassium ferricyamide. In all cases an immediate precipitate of Prussian blue was formed. One or two drops were added to a mixture consisting of a few drops each of carbolic acid and strong sulphuric acid. A reddish-yellow coloration ensued in all cases. On standing for several hours this color changed to permanent violet. The remainder of the aqueous mixture was, at a single dose, given to a small kitten. In no case could any ill effects be observed. Since tyrotoxicon has been shown by Dr. Vaughan to be such an active poison, it was concluded that the reactions mentioned above must have been due to other causes. In looking for these causes it was found that commercial butyric acid could be made to produce both reactions in a satisfactory manner, as will be seen from the following tests:

A single drop of the butyric acid produced only a slight formation of Prussian blue when added to a mixture of ferric chloride and potassium ferricyanide.

With a single drop of the butyric acid the carbolic acid reaction was very marked, the mixture immediately turning bright orange-red, and changing to dark violet on standing.

One-half cubic centimetre of the butyric acid was mixed with 50 c.c. of water and filtered. The filtrate was rendered strongly alkaline with sodium carbonate, extracted with ether, and the ether allowed to evaporate spontaneously. The aqueous residue gave both reactions with marked distinctness.

Again, the last sample of cheese examined was allowed to remain in the percolator. The bottom of the percolator was corked, the cheese covered with distilled water, and the mouth of the percolator covered with a glass plate. After standing four or five days further decomposition had set in. The aqueous extract was then withdrawn and filtered. The filtrate was alkaline and had an offensive odor. It was placed in a flask connected with a condenser, and a portion distilled over. This was done to destroy any tyrotoxicon that might have been present. The distillate was very alkaline, and had a strong, sickening odor of herring brine, probably due to trimethylamine. From this distillate both reactions were obtained, the Prussian blue reaction being especially marked.

The residue left in the flask was removed, acidulated with sulphuric acid, and filtered. The filtrate was again subjected to distillation. The distillate was acid and had a strong odor of butyric acid. It gave no Prussian blue reaction, and only a faint one with carbolic acid. A portion of this distillate was rendered alkaline with sodium carbonate and extracted with ether. The residue gave no reaction whatever with carbolic acid, owing evidently to the fact that the sodium butyrate is insoluble in ether. The remainder of the acid distillate was then mixed with the alkaline distillate obtained above. The mixture was rendered alkaline with sodium carbonate, and then extracted with ether. The aqueous solution now gave both reactions very distinctly.

From these experiments it may be inferred:

1. That the Prussian blue reaction is caused by the presence of an organic base, probably an amine.

2. That the carbolic acid reaction is due to butyric acid.

3. That, when both bodies are present in the same liquid both are extracted with ether from an alkaline solution, probably in the form of a butyrate of the organic base.

4. That both bodies are liable to occur in any old specimen of milk, cheese, or cream.

5. That the presence of these two bodies causes artificial diazo-benzole to give the orange red reaction with carbolic acid, after being extracted from whey with ether, which it does not give before.

Diphtheria in Detroit.—The President of the Board of Health of the city of Detroit, Mich., in his annual report, stated that in nine years two thousand two hundred and fifty deaths from diphtheria had been reported. The inefficiency of sulphur fumes for disinfection was also strongly emphasized.

Very Large Doses of Iodide of Potassium in inveterate syphilis have long been employed by American physicians. In the *Sémaine Médicale* Dr. Wolf, of Strasburg, reports a number of cases in which ordinary doses having proved useless, as much as an ounce and two-thirds per diem was administered. The patients promptly improved under these heroic doses, and their body-weight is said to have considerably increased while taking pounds of the iodide.

SIMPLE EXTRACTION OF CATARACT WITHOUT IRIDECTOMY.[1]

BY CHARLES STEDMAN BULL, A.M., M.D.,

PROFESSOR OF OPHTHALMOLOGY IN THE UNIVERSITY OF THE CITY OF NEW YORK; SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY; CONSULTING OPHTHALMIC SURGEON TO ST. LUKE'S HOSPITAL AND TO ST. MARY'S FREE HOSPITAL FOR CHILDREN.

THE writer apologizes for presenting this third paper on simple extraction of cataract, and offers as an extenuating plea a more extensive experience in the operation. A previous paper on the subject, based upon the detailed report of one hundred cases, was read before the New York State Medical Association, in September, 1889. Since then the writer has continued to operate by this method on all cases which were deemed suitable for it; and an increased experience, while leading him to modify some of the views previously expressed, has in the main confirmed him in the justice of the claims advanced in favor of the operation. The controversy as to the wisdom or necessity of an iridectomy in the extraction of cataract is still unsettled; but as time goes on and our experience increases, our knowledge upon this point, as upon others, becomes crystallized into something like a positive opinion. It is interesting to compare the views of such men as Schweigger, Sattler, and Meyer, on this subject, as already published. Schweigger starts out with an assumption, in reference to the corneal section, which we all admit, viz., if an incision with a sizeable flap is to be made with the narrow knife, it can only be completed by a to-and-fro sawing motion. Every turn of this narrow knife in the wound makes the course of the incision irregular, and must retard the healing. A smooth healing of the wound means the avoidance, as far as possible, of an irregular corneal curvature, which is generally recognized as the greatest cause of imperfect vision after extraction with iridectomy. He considers that there is great danger of prolapse of the iris after such a flap extraction, and hence he argues that it is better to make the corneal section in the inner margin of the limbus, and not too peripheral. He believes in using a binocular bandage in all cases where an iridectomy is not made, and thinks that the eye should not be opened for three days at least, all drops being instilled in the angle of the lids without opening them. He considers that the disadvantages of a prolapsed iris consist mainly in the great irregularity of the corneal curvature. If the prolapse is large, he cuts it off. If it is small, he thinks it better to leave it undisturbed, for these small prolapses become flattened in the course of cicatrization, with an improvement in the corneal curvature. He believes that the presence or absence of an iridectomy makes very little difference in regard to the acuity of vision, and in so far as this remark refers to central vision, the writer agrees with him, for the latter depends much more upon the irregularity of the corneal curvature caused by the incision. Schweigger uses a capsule-forceps for opening and removing a piece of the anterior capsule. He uses a triangular knife, shaped something like the old Beer's knife, for making the corneal section. This knife is 7 mm. wide at a distance of 30 mm. from the point, and with it he makes a corneal flap 4 mm. in height. In sixty cases of extraction made with this knife, prolapse of the iris occurred in five cases.

Sattler, of Prague, makes his flap include one-third of the corneal circumference, the incision being entirely in the cornea. He also uses a capsule-forceps for opening and removing a piece of the anterior capsule. By the simple method he removes all hard, or homogeneous, or brownish-gray cataracts, and also all immature cataracts which can be removed entire from the capsule. If the case is one in which the cortex is probably friable, and cannot therefore be removed with the nucleus, he always performs an iridectomy. He agrees with Schweigger in the wisdom of not looking at the eye too soon after operation. Sattler has found more corneal astigmatism after the simple extraction than after the peripherical linear extraction with iridectomy, and in this view the writer agrees with him. He prefers the narrow knife in operating.

Meyer also prefers the narrow knife of Von Graefe for making the flap operation, and the narrower it is, the better he likes it. He makes his section entirely in the limbus, and endeavors to remove a piece of the anterior capsule. He exercises great care in bandaging the eyes, and his first bandage is left on forty-eight hours. Meyer makes a good point when he states that with prolapse of the iris incarceration is always left behind, even after complete abscission of the prolapsed iris.

Preparation of the Patient.—If the patient be a hospital case, he should have a bath of the entire body on the morning of the operation, special attention being paid to the cleansing of the hair and beard with soap and water. This is not considered necessary in the case of a private patient. Just before the operation the patient's face should be carefully washed with soap and water, and then laved with a solution of mercuric bichloride (1 to 5,000). A saturated solution of boric acid should then be used for irrigation of the conjunctival cul-de-sac. The patient should be placed in the bed which he is to occupy throughout the entire course of treatment, so as to avoid all unnecessary moving about. This precaution reduces to a minimum the dangers which may arise from prolapsed iris, opening of the wound, loss of vitreous, hemorrhage, etc. The writer attributes to this one precaution, as much as to any other, the immunity from secondary prolapse which his experience shows.

After the necessary local anæsthesia has been produced by a few drops of a five per cent. solution of cocaine hydrochlorate, the conjunctival cul-de sac is again thoroughly irrigated with the boric acid solution, and the patient is then ready for operation.

The instruments are all previously cleansed and sterilized in boiled water and placed in a bath of alcohol. From this bath they are taken, wet, as they are wanted for the operation. The hands of the operator and of the assistant, if he has any, are carefully cleansed with soap and water, and then washed with a solution of mercuric bichloride (1 to 2,000).

The writer sits behind his patient, and operates on the right eye with the right hand, and on the left eye with the left hand. In this way he is never in his own light. If the operator is not naturally ambidextrous, he should strive to make himself so. A speculum is then introduced to hold the lids open, and the eyeball is firmly grasped with a pair of fixation-forceps, the latter being made to seize the conjunctiva and subconjunctival tissue over the insertion of one of the straight muscles of the eye, usually the inferior rectus.

[1] Read before the American Ophthalmological Society, at its annual meeting, July 16, 1890.

A straight, narrow knife, somewhat more slender and delicate than the cataract-knife of Von Graefe, is then introduced on the temporal side in clear cornea, near the limbus, and is passed quickly across the anterior chamber, horizontally, in front of the iris, and is brought out at a corresponding point in clear cornea on the nasal side, and the incision is then completed, if necessary, by a to-and-fro movement. The length of the incision should involve about two-fifths of the circumference of the cornea, and is always an upward section. The incision should be entirely in clear cornea, and the flap should be large enough to admit of the easy extrusion of a large lens. The writer feels sure that a too peripheric location of the corneal section favors both prolapse and incarceration of the iris. The writer never makes a conjunctival flap if it can be avoided, as he regards it as a useless complication, unless the patient has a chronic conjunctivitis or dacryocystitis, and it undoubtedly increases the danger from primary infection by enlarging the wound. Furthermore, in order to make a conjunctival flap the corneal incision must be well in the limbus, and to this is raised the objection already referred to—the greater tendency to prolapse or incarceration of the iris if the wound is peripheric. In making the corneal section care should be taken to pass the knife quickly across the anterior chamber, and thus complete the section as rapidly as possible. This prevents the escape of aqueous almost entirely, and there is but little danger that the iris will fall over the edge of the knife and be divided.

The writer formerly advised that, in case the iris prolapsed outside of the wound as soon as the section was completed, it was better to restore it to its place in the anterior chamber before opening the capsule. This step he now regards as an unnecessary manipulation of the iris that might cause additional bruising in unskilled hands. As a matter of experience, the iris rarely prolapses until pushed out by the extrusion of the lens.

The capsulotome is then introduced and carried well behind the inferior margin of the sphincter of the iris, and the capsule is lacerated by a T-shaped incision, or, better, by a quadrilateral one, care being taken to avoid wounding the iris. The object of the quadrilateral incision in the capsule is not only to make a free opening for the passage of the lens, but also in hopes of effecting a possible removal of this square piece of the anterior capsule with the lens, and this, in many cases, succeeds. The capsule-forceps have also been employed for the purpose of removing a piece of the anterior capsule, and often with success, though not always so. When the latter fails to remove the piece of capsule, the opening made is not sufficiently wide, and must be enlarged with the capsulotome. The speculum is then removed, so as to avoid all undue pressure on the eyeball, and this is to be regarded as a wise precautionary step in view of any possible straining by the patient.

The extraction of the lens then follows. This may be done in two ways, viz.: 1. The upper lid may be lifted up away from the eye by a wire elevator or a broad strabismus hook, and the lens expelled by pressure with a spoon upon the lower portion of the eyeball, and thus indirectly on the lens, backward toward the centre of the eye at first, and then upward and backward. In this way the flap rises, tilts forward, and the lens passes through the pupil with the least bruising of the iris. 2. This may be effected by pressure on the eye above the wound with a narrow spoon or spatula, and counter-pressure on the lower portion of the cornea with a broader spoon. This causes a gaping of the wound and a revolution of the lens upon its horizontal axis, the upper margin of the lens coming forward and presenting in the wound. A brief continuance of this pressure and counter-pressure causes the extrusion of the lens, and a more or less extensive prolapse of the iris.

The removal of the speculum before the extraction of the lens should always be done in cases of complicated cataract; especially when the suspensory ligament is defective and the vitreous disorganized, or the lens partially dislocated.

The next step in the operation is the removal of the remnants of soft lens matter or cortex from the anterior chamber and between the lips of the corneal wound. The removal of the cortex can usually be accomplished by rapid and judicious following up the escape of the lens by pressure with the spoon upon the lower portion of the cornea, and also with the lower lid. If this does not succeed, it is better to make repeated and continuous rotary massage of the lid upon the eyeball, aided by repeated slow movements of the curette, spoon, or spatula over the cornea from below upward toward the wound. These manœuvres should be accompanied by frequent irrigation of the conjunctival cul-de-sac and lips of the wound, and even of the anterior chamber if necessary, by a warm saturated solution of boric acid. Solutions of mercuric bichloride should never be used for irrigation of the anterior chamber, as they cause transient opacities on the internal surface of the membrane of Descemet in the endothelial cells. It is very rarely necessary to introduce any instruments into the anterior chamber for the purpose of removing bits of cortical lens matter. For irrigation of the anterior chamber any small lachrymal syringe may be used, but it should always be sterilized and kept exclusively for the purpose. The nozzle should be carefully introduced between the lips of the wound, and the fluid should be injected very slowly and gently, and in small quantities.

The next step is the replacing of the prolapsed iris, which occurs spontaneously in about half of the cases. Among the first one hundred cases reported by the writer the iris was replaced spontaneously in fifty-six cases. If the iris has not spontaneously replaced itself during the manipulations employed for removing fragments of cortex from the anterior chamber, it may be readily replaced by gently stroking and pushing it within the lips of the wound with a smooth probe or spatula. If on reduction of the prolapsed iris the pupil is neither central nor round, do not make an iridectomy at once, as some surgeons advise, but endeavor, by a careful, gentle, and continuous rotary massage of the eye through the closed lids, to bring about such an absolute replacing of the iris in its normal position as will make the pupil round and central.

The final steps in the operation, before the application of the bandage, are a careful irrigation of the lids and conjunctival cul-de-sac with the saturated solution of boric acid, and the instillation of a few drops of a solution of eserine sulphate (half a grain to the ounce) into the cul-de-sac. The writer again takes advantage of the opportunity to warn against using solutions of eserine of any greater strength than half a grain to the ounce in the eye. He has seen during the past year several bad cases of iritis directly caused by solutions of two and four grains to the ounce of water. In many cases a solution of one-tenth of a grain is strong enough to produce any desired contraction of the iris, and no risk is here run of producing any irritation.

The lids of both eyes are then closed, and covered with a piece of coarse-meshed cotton or linen saturated in a solution of mercuric bichloride (1 to 5,000). Over this is laid a pad of antiseptic absorbent cotton, and a double-roller flannel bandage is applied over both eyes.

The after-treatment should vary with the temperament and general condition of the patient and the nature of the case. The patient should be kept in bed on an average for three or four days, but may be allowed to sit up in the bed while eating and at other times, in order to avoid inducing fatigue in his back. He should be allowed to rise from bed to answer the calls of nature. Both eyes are to be kept bandaged for a varying period, according to circumstances. The room need not to be darkened. The bandage and dressings are to be removed at the end of forty-eight hours, and sooner if any reason for so doing arises. The edges of the lids are to

be gently cleansed with a warm saturated solution of boric acid, or a warm solution of mercuric bichloride (1 to 5,000), and the lids are then gently opened and the eye is inspected. If the pupil is still contracted, a weak solution of atropia (one grain to the ounce) is instilled for the purpose of preventing as far as possible the formation of posterior synechiæ, which occur in about sixty per cent. of the cases. If there is any mucous secretion, or any swelling of the lids, the cul-de-sac and eyeball must be thoroughly and carefully irrigated with the warm boric acid solution, and an inspection of the whole length of the wound made. If on the contrary there is little or no secretion, and if the lids look well, the eye need not be inspected until the fourth or fifth day, but the dressings should be renewed and the lids cleansed daily. If on the fourth or fifth day the pupil is round and central, the eye is carefully irrigated, and if the wound has closed throughout its entire length, the bandage is discontinued during the day, and at night is replaced, but only on the operated eye. The eye not operated upon is usually left uncovered after the second or third day. Should there be any pain or circumcorneal injection present, a weak solution of atropia should be used several times a day until both these symptoms have subsided. The writer considers it a mistake to give the cataract patient too much liberty, and in this respect Wecker and Panas, in Paris, and some of our own American surgeons have decidedly erred. When patients are sent home on the day of operation, or discharged from treatment in two or three days, any report of the result obtained in such cases is valueless, and detailed statistics are impossible. The court-plaster dressing without a bandage has been tried by the writer and found wanting. It is irritating to the skin of the lids and has been abandoned. The binocular roller bandage should be put on with great care. In warm weather it is better to use a roller bandage of linen or cambric gauze, which is much less heating than flannel.

Complications Occurring in the Course of the Operation.—1. The iris may fall upon the edge of the knife in its passage across the anterior chamber, and may be wounded or excised as the corneal section is completed; the accident may happen to any surgeon, and is much more likely to occur if the patient strains or contracts any of the muscles of the eye or the orbicularis. The rapid passage of the knife across the anterior chamber to its point of exit in the cornea on the opposite side, and the avoidance of any undue pressure on the eyeball by the fixation-forceps, will do much toward preventing the occurrence of this accident. The rapid completion of the corneal section also aids in this endeavor, and is very necessary to the making of a smooth operation. Should the iris be cut or excised in this first step of the operation, an iridectomy must be done at once, and the artificial pupil made clean and smooth. As a matter of fact, this accident rarely happens to the skilled operator.

2. *More or less Extensive Hemorrhage into the Anterior Chamber.*—This may be in great part prevented by avoiding the formation of a conjunctival flap. If the hemorrhage comes from a wounded iris, the latter is to be smoothly excised, and the hemorrhage from the divided vessels must then be controlled, and the blood, as far as possible, removed from the anterior chamber, before the further steps of the operation are completed. The presence of the blood in the anterior chamber interferes with the proper laceration of the capsule and the removal of the lens.

3. Retraction of the iris toward the ciliary processes, or its dilatation and folding away into the upper part of the angle of the anterior chamber. This is not a common accident, but it is an awkward complication of the subsequent healing process. After the lens has been extracted and the anterior chamber thoroughly cleansed, the retracted iris may sometimes be made to assume its normal position by continuous rotary massage of the eyeball, assisted by a drop or two of eserine. It may also be sometimes replaced by very careful and delicate stroking with the end of a hard rubber spatula. If the iris is crowded up into the angle of the anterior chamber, it is better at once to pull it out of the wound and cut it off. In any event the necessity of an iridectomy is an unfortunate complication, for owing to the location of the wound in the cornea, at some distance away from the periphery, it is not possible to make a perfectly smooth coloboma.

4. *Prolapse of the Vitreous.*—This may occur at any step of the operation, and is always a misfortune. In the hands of a careful operator it is usually slight, especially if the speculum has been removed after the opening of the capsule, and it need not interfere with the usual careful manipulations employed in evacuating the lens. Any portion of vitreous that remains in the wound after the lens has been removed must be immediately cut off close to the wound, and great care must then be exercised in any manœuvres undertaken for removing any fragments of cortex from the anterior chamber. In case of prolapse of the vitreous, all irrigation of the anterior chamber must be avoided, as it would certainly increase the loss of vitreous. If the latter is fluid and the prolapse extensive, the lens should be removed at once with the blunt hook or spoon, and the eyelids immediately closed temporarily for a few minutes. The iris should then be replaced, gentle irrigation of the cul-de-sac should be done, eserine instilled, and the eye then closed with the usual antiseptic dressings and bandage.

Complications of the Healing Process.—1. Posterior synechiæ, or adhesions of the posterior surface of the iris to the remains of the anterior capsule of the lens, occurring independently of any actual iritis. These adhesions are very common, being met with in at least sixty per cent. of the cases. They are in many cases filiform or thread-like in character, and rarely obstruct the pupillary area. They are caused by the edges of the lacerated anterior capsule coming in contact with the sphincter margin of the iris, which has already been somewhat bruised by the passage of the lens through the pupil.

2. *Iritis.*—Almost always of the mild, plastic type, occurring but seldom (less than eight per cent. of the cases), and sometimes involving only a segment of the iris. This is best treated by weak solutions of atropia and warm applications.

3. *More or Less Complete Obstruction of the Field of the Pupil by the Opaque or Thickened Capsule of the Lens.*—This is a very common complication of the healing process, not only in the simple extraction, but in all forms of extraction. It almost always requires operative interference of some kind, usually discission, in order to give satisfactory ultimate vision. In the experience of the writer, discission is demanded in at least two-thirds of the cases.

4. *Incarceration of the Iris or Anterior Synechiæ.*—This consists in a more or less marked adhesion of the iris to or in the inner lips of the wound. This condition should be carefully distinguished from actual prolapse of the iris, where the iris either entirely fills the wound or is actually prolapsed outside of it. This complication unfortunately occurs too often after simple extraction, the writer having met with it in fifteen of his first one hundred cases. Since then he has met with it less frequently, and this is probably due to the less peripheric location of the corneal wound in his later operations. These adhesions may sometimes be diminished, or even broken, by using a half-grain solution of eserine several times a day, but the risk of exciting irritation in the iris, and actual inflammation, militates against any prolonged use of the drug. An incarceration of the iris is an unfortunate complication, for it distorts the pupil and may be a source of irritation to the eye; but its danger may be reduced to a minimum by making the entire length of the section in clear cornea.

5. A more or less irregular pupil, usually oval, caused by a puckering of the iris in the upper part of the angle of the anterior chamber, without any actual adhesion or incarceration of the tissue of the iris in the lips of the

wound. There seems to be no certain means of averting this, and it does not appear to exert any unfavorable influence upon the vision.

6. *Secondary Prolapse of the Iris.*—This is almost always of traumatic origin, that is, due to some sudden or unexpected movement or act on the part of the patient, such as lying on the operated eye and thus opening the wound, or displacement or actual removal of the bandage by the patient. It may perhaps be sometimes due to a premature opening and examination of the eye by the surgeon. It is probably safe to say that its prevention depends on careful nursing, and partly also on the location of the corneal section. If the incision is in the limbus, prolapse of the iris would be more likely to occur than if the incision were in clear cornea away from the limbus. The views of the profession have changed in regard to the necessity of cutting off all prolapses of the iris. Formerly all were abscised, but now we reason differently. If the prolapse occur soon after the operation and it cannot be reduced, it should be cut off as neatly as possible, and the edges gently stroked into place in the anterior chamber. If the wound has already partially closed, and the prolapse of the iris is a late occurrence, it is better to leave it undisturbed. Many, if not all of these prolapses, when left to themselves, disappear or cicatrize in a smooth manner, and are not specially apt to give rise to any sympathetic trouble. Great care in operating, and the strict exclusion of all such unsuitable cases as rigidity of the iris, dislocation of the lens, unmanageable patients, will all aid in reducing the cases of secondary prolapse of the iris to a minimum.

7. *Capsulitis*, or inflammation of the capsule of the lens, is a somewhat rare complication. It is almost always of the mildly plastic character, and is usually associated with the mild form of iritis. If it is of the suppurative type, it is almost always, if not invariably, accompanied by a purulent inflammation of the iris and infiltration of the tissue of the cornea in the vicinity of the wound, and is always the result of secondary infection from without, the purulent infiltration beginning in the wound.

8. *Purulent Infiltration of the Lips of the Corneal Wound.*—This cloudiness of the lips of the corneal wound is fortunately a very rare complication, thanks to modern cleanliness and antiseptic precautions. It is always the result of secondary infection from without, and if not attacked at once by energetic measures it may end in total loss of the eye from suppurative panophthalmitis. The writer has met with it but three times in something over one hundred and sixty operations, and in all those cases it was almost immediately checked. Its origin is usually a chronic conjunctivitis or dacryocystitis, and it should be treated energetically by an immediate removal of the bandage and dressings, repeated irrigation of the wound, eyeball, culs-de-sac, and inner surface of the lids with a hot solution of mercuric bichloride (1 to 5,000), and prompt cauterization of the entire length of the wound by the galvano-cautery. The latter may be repeated daily for several days, if necessary, or as long as it seems to influence the course of the suppurative process.

Secondary Operations.—It is often necessary to perform secondary or after-operations in order to improve the vision, after the cataract has been extracted, and these secondary operations may be divided into two classes; viz.:

1. Discission or laceration of the posterior capsule.

2. Excision of a piece of thickened capsule, or of a piece of membranous or pseudo-membranous tissue, composed of the thickened posterior capsule and the products of inflammatory exudation. A subsequent division of the capsule, some weeks after extraction, plays almost as important a part in restoring the ultimate vision as the extraction of the cataract itself. All after-operations should be done with great care and under strict antiseptic precautions, and when so done there is usually but little reaction following them. The gain in visual acuteness following a secondary operation is often very great.

1. Discission or laceration of the posterior capsule is very often, perhaps in the great majority of cases, necessary, and almost never dangerous in the hands of a skilled operator. The best instrument probably for this operation is the slender, sharp, curved knife-needle with cutting edge. This is plunged through the cornea, near the limbus, on either side, wherever it seems most indicated, and the capsule is lacerated by a single vertical or transverse stroke of the blade, or, if necessary, the opening is made crucial. Under cocaine this may be done without the employment of fixation-forceps, and thus all undue pressure on the eyeball is avoided. The difficulty and danger of the operation are of course proportionate to the density and position of the membrane to be divided. When it is possible, the writer prefers to employ the electric light for this purpose, as with this intense illumination the faintest cobweb of a capsule may be seen and readily lacerated. A capsule which has been thickened by the products of inflammation, such as is met with after iritis or iridocyclitis, cannot safely be approached in this way, and for such cases we resort to the more serious operation of excision.

2. Excision of a piece of thickened capsule or pseudo-membrane, which blocks the field of the pupil, and its removal from the interior of the eye. This class of cases should be studied with great care before deciding upon what is to be done. When it has been decided that a piece of the capsule or pseudo-membrane must be removed, an incision should be made in the cornea near the limbus, and over that part of the membrane which it is proposed to remove. This incision may be made with a narrow cataract-knife, or a Beer's knife, or, better still, with a straight lance-knife. If the membrane is very thick, the knife may be plunged through it from the periphery toward the centre, at the same time that the corneal incision is made. Sometimes by this manœuvre the thickened capsule gapes sufficiently to admit of decidedly improved vision without the necessity of removing a piece of it. More often this, however, does not occur, and then the next step is to insert a Tyrrel's hook, catch and draw out a flap of the thickened capsule, and cut it off close to the wound in the cornea. Another way of performing this second step, is to introduce a fine pair of Wecker's knife-scissors through the corneal wound, and then excise and remove a triangular piece of the thickened capsule or membrane. This is decidedly a more difficult and dangerous operation than the simple discission, as it may set up a fresh attack of iritis or iridocyclitis, with subsequent closure of the opening made in the capsule by the knife, or somewhat rapid atrophy of the eyeball.

The manœuvre of opening the capsule with the point of the cataract-knife while making the corneal section is not to be commended. It is the revival of a method practised many years ago by Wenzel and others, the capsule being split horizontally in the upper portion of the pupillary space. It was at that time claimed that it simplified the operation of extraction by lessening the number of instruments required for the operation. It is not an easy manœuvre to perform, and may make an irregular and ragged corneal wound, thus protracting the healing process, and also rendering the wound more liable to secondary infection. If the capsule happened to be thick and tough, the point of the knife might fail to open it sufficiently, and there might be some danger of rupture of the suspensory ligament and partial dislocation of the lens. This manœuvre is very difficult if the pupil is narrow and the anterior chamber shallow, and the iris should almost certainly be wounded.

The difference between primary and ultimate vision is enormous, and the gain in the latter is due to the secondary operation. Moreover, the ultimate vision, after discission, becomes even better as time goes on, and as the cloudiness of the vitreous, following the operation, clears up. Furthermore, it should not be forgotten that many cataractous eyes have a more or less unhealthy fundus. There is more or less disease or degeneration of the

choroid in almost all elderly people, and the more extensive this choroidal degeneration is, the more likely is the retina to be involved in the process. These eyes would, of course, have a diminished visual acuity, entirely distinct from the loss of vision due to the presence of cataract. Hence we should not be surprised at the low degree of visual acuity in many cases after a successful extraction of cataract; and if the vision cannot be improved by careful correction of the existing astigmatism as well as the aphakia, we should look for the cause of the failure in some existing lesion or degeneration in the fundus.

A Comparison of the Advantages and Disadvantages of Simple Extraction of Cataract.—The advantages of simple extraction may be summed up as follows:

1. If successful and without complication, it preserves the natural appearance of the eye—a central, circular, and movable pupil.

2. The acuteness of vision, with the astigmatism carefully corrected, is somewhat greater than after the old operation.

3. Eccentric vision and orientation are decidedly better than by the old operation.

4. Small particles of capsule are much less likely to be incarcerated in the wound, and thus act as foreign bodies and excite irritation.

5. It is a shorter operation in point of time, by reason of the absence of an iridectomy.

6. As there is no iridectomy, there is little or no hemorrhage, and this may be considered a very decided advantage. How often do we see an operation for the extraction of cataract delayed, sometimes for many minutes, by extensive extravasation of blood from the divided blood-vessels of the iris, often filling the anterior chamber and becoming coagulated. Many an operation has been interrupted, and the extraction of the lens postponed to a future day, because the hemorrhage from the iris was so profuse as to render the further steps of the operation well-nigh impossible, until the blood in the anterior chamber had been absorbed. If blood remain in the anterior chamber after the opening of the capsule and the extrusion of the lens, the coloring matter frequently is deposited in the lacerated capsule, and by its dark color interferes considerably with the ultimate vision.

The disadvantages of simple extraction are as follows:

1. The technique of the operation is decidedly more difficult than that of the old operation. The corneal section must be larger, in order that the passage of the lens through it may be facilitated, as the presence of the iris acts as an obstacle to its passage. The section must be performed rapidly, so as to avoid the danger of the iris falling on the knife and being wounded. This rapid passage of the knife across the anterior chamber renders it difficult to make the height of the flap an even curve, particularly when the incision is entirely in clear cornea, as it should be. The cleansing of the pupillary space and the posterior chamber is much more difficult than after the old operation.

2. Posterior synechiæ, secondary prolapse, and incarceration of the iris are more frequently met with than after the old operation. The two latter may be largely avoided by making the corneal section, as before stated, in clear cornea, and not in the limbus, which is too peripheral, and rather favors both prolapse and incarceration of the iris.

3. The operation is not applicable to all cases. This objection, however, may be applied to all operations.

Dysentery in the German Army.—It is said that dysentery is just now very prevalent among the soldiers in Germany. Energetic measures have been ordered for the purpose of circumscribing the epidemic, and the use of unboiled drinking-water has been forbidden in the affected regiments.

SURGERY OF THE LATERAL VENTRICLES OF THE BRAIN.[1]

By W. W. KEEN, M.D.,

PROFESSOR OF SURGERY IN THE JEFFERSON MEDICAL COLLEGE, PHILADELPHIA, PA.

After alluding to the fact that puncture of the brain for the relief of hydrocephalus dates back to 1744, in the case of Dean Swift, Dr. Keen pointed out that the former operations were done through the anterior fontanelle, and not by trephining.

In 1881 Wernicke first proposed to trephine and puncture the lateral ventricles. This proposition was enforced by Zenner, of Cincinnati, in 1886.

On November 7, 1888,[2] Dr. Keen read a paper before the College of Physicians of Philadelphia, in which, in ignorance of these earlier propositions, he proposed to trephine, puncture, and drain the lateral ventricles. He was led to this by a case of exploratory trephining for supposed abscess of the temporo-sphenoidal lobe. The post-mortem showed that there was distention of the lateral ventricles in consequence of tubercular meningitis, that the drainage-tube had reached to within a quarter of an inch of the ventricle, and had not produced any inflammation. He pointed out the fact that the brain would bear pressure much less well than the other viscera, and hence the need for early trephining. He then reported the following three cases of his own:

Case I.—A boy, four years of age, was threatened with blindness from acute hydrocephalus. This condition was judged to be due probably to tumor of the cerebellum, though on which side was doubtful. Dr. Strawbridge had examined the eyes, and had found that there were choked discs with retinal hemorrhages and swelling. The swelling of the disc measured 2.30 mm. in each eye, and, in view of the rapidly increasing blindness, Dr. Strawbridge brought the child to Dr. Keen for the performance of an operation. This was done at the Woman's Hospital, Philadelphia, January 11, 1889. A puncture was made at a point one inch and a quarter behind the left meatus, and the same distance above "Reid's base-line." A half-inch button of bone was removed and the brain punctured by a hollow needle (No. 5, French catheter scale), which was inserted in the direction of a point two and a half inches vertically above the opposite meatus. At about an inch and three-quarters the resistance suddenly ceased, and the cerebro-spinal fluid began to escape. Three stout horse-hairs, doubled, were then passed into the ventricle. No phenomena occurred during the operation. The highest temperature that followed the operation was 101.2° F. for a very brief interval, but most of the time it was normal. In two days the swelling of the optic nerves had fallen to 1.57 and 1.63 mm. in the right and left eye respectively, and, by the sixth day, to 1.09 mm. in both eyes. By the seventh day the swelling of the optic nerve had increased, and the drainage was not very free. The tumor was sought for by probing through the drainage opening into the occipital lobe, almost to the occipital bone. No tumor being found by probing, an opening a quarter of an inch in diameter was gouged in the occipital bone below and to the left of the inion. The cerebellum was explored by a probe to the depth of two and a quarter inches in the direction of the left lobe, and again obliquely across into the right lobe, but no tumor was found. This wound healed by first intention without any fever.

On the fourteenth day the horse-hairs were removed, and a small rubber drainage-tube was inserted into the ventricle in order to give freer vent to the fluid. This was attended by no pain or discomfort. By the twenty-eighth day the child had become somewhat restless, and the swelling of the discs, which had fallen to 0.83 mm., had again increased to 1.33 mm. in each eye. Accordingly, the right side of the skull was trephined at the corre-

[1] Résumé of paper read before the Surgical Section of the Tenth International Medical Congress, Berlin, August, 1890.

[2] Medical News, December 1, 1888.

sponding point above and behind the ear, and the occipital lobe was punctured to the tentorium, but no tumor was found. A drainage-tube was then passed into the right ventricle directly, being inserted without prior puncture, by a hollow needle.

On the thirty-second day, by a fountain syringe, the bag of which was raised about six inches above the head, the ventricles were irrigated from side to side with warm boric acid solution, four grains to the ounce. While the connection was being made with the tube, the child was a little restless, but so soon as the warm water began to flow into the brain he became quiet, and said that "it felt good." The fluid escaped from the opposite side slowly. The bag of the syringe was then elevated until the escape became quite free, but never reached a continuous stream. It was estimated that about eight ounces passed into the ventricles, of which about two ounces escaped from the opening on the opposite side, and about six ounces were retained. No phenomena whatever was apparent during the process described, saving the comfort shown by the child.

On the thirty-fourth day the ventricles were again irrigated from side to side with plain boiled water, which gave less relief than the boric acid solution, but produced no ill effects. A few days later the child was evidently not so well, and died on the forty-fifth day, the first drainage-tube having been in place nearly all that period.

At the autopsy the cerebro-spinal fluid was perfectly clear, more so than that which was obtained at the first tapping, which was slightly turbid. The ventricles were greatly distended with fluid. There was found in the left lobe of the cerebellum a sarcoma, which had compressed, as was suspected, the straight sinus and the veins of Galen, and had encroached on the fourth ventricle. The sinuses through which the rubber tubes passed were not surrounded by an inflammatory zone. There was no injury of the opposite wall of the ventricle, and no trace of the punctures made in the cerebrum or cerebellum. The oblique puncture made in the latter had gone through the tumor, which, however, was too soft to be perceived.

CASE II.—A boy, aged three and a half years. Hydrocephalus set in four or five months after birth. His mental condition was extremely poor. On March 5, 1889, the left ventricle was tapped in the same manner as in Case I. At a depth of an inch and a quarter the resistance suddenly ceased, and the cerebro-spinal fluid immediately escaped. As in the first case, the fluid was slightly turbid. Drainage by horse-hairs, as formerly, was not very effective. The highest temperature immediately after the operation was 100.2° F., and there was marked increase in the use of the right arm, which had been paretic. The drainage being insufficient, on the fourth day the ventricle on the opposite side was opened, and a small drainage-tube inserted in both ventricles. These were stopped by disinfected plugs of wood, with a V-shaped slot cut in each, so as to allow of the escape of the fluid at about thirty-five drops a minute. As this seemed to be too free, after four and a half hours other disinfected plugs were inserted, with smaller slots. Convulsions set in the next day.

As soon as Dr. Keen reached the patient he found the convulsions constant, so he decided to replace the drained fluid, and having no time for the preparation of an artifical cerebro-spinal fluid, he used plain boiled water. This was siphoned from a height of about eight inches. As soon as the warm solution began to flow into the ventricles the spasms ceased. The flow was then immediately stopped by squeezing the tube, and in a few minutes the convulsions returned. They were immediately arrested again by slight siphonage of warm water. Eight times the convulsions returned, and each time they were arrested by a siphonage of about one-half ounce to one ounce of fluid. Dr. Keen estimated that the amount of fluid injected was nearly a pint. No further spasms occurred, but the child gradually failed, and died in the afternoon. The autopsy showed great hydrocephalic distention, but no injury from the operation.

CASE III.—This was a case of tubercular meningitis with unilateral acute internal hydrocephalus of the left ventricle. The foramen of Monro, as the autopsy showed, was closed. This closure was attended by left unilateral distention and produced right hemiplegia. In this respect the case is probably unique. The left ventricle was tapped through the arm-centre. The child was almost *in extremis* when it was done, and died about four hours after the operation. At this operation it was equally easy to determine when the ventricle was reached.

Dr. Keen next referred to the case of von Bergmann, in his "Surgical Treatment of Brain Lesions," as the first case ever operated upon, though not published until after his own paper and a note upon his first case. This case was operated on July 15, 1887, by the anterior route, and proved fatal on the fifth day. He described, next, two cases reported to him by letter, by Mr. Mayo Robson, of Leeds, as follows:

A girl, aged ten, without preceding illness, began to have pain in the left ear, and was feverish, December 19, 1888. In three days a discharge followed, which gradually lessened, but was still present a month later when admitted to the hospital. There had been also rigidity of the neck and twitching of the right angle of the mouth; no vomiting. Slight mental disturbance. On admission, January 19, 1889, temperature 105° F.; pain in left side of head, paresis of right arm and leg, gradually developing into complete hemiplegia and aphasia. Optic discs inflamed. Operation, February 7, 1889. Trephining over the arm-centre. Dura healthy. On exposing the brain it did not pulsate and seemed to be compressed. Exploring-needle passed deeply in various directions, hoping to reach pus, but failing to find any the needle was pushed on into the lateral ventricle and a half ounce of clear fluid drawn off, after which pulsation returned in the brain.

The wound was closed as usual, no drainage being employed. The next day there was slight power in the arm, soon after in the leg, and on the third day she could answer simple questions. Within a month the hemiplegia was gone. Six months later she was perfectly well.

Even a half-ounce of fluid seems to have imperilled life by pressure, and the operation undoubtedly saved her life, a more important and encouraging lesson for the future.

Mr. Robson's second case was one of an infant, who was trephined for quickly increasing hydrocephalus, following treatment of spina bifida by Morton's injection. The skin was trephined an inch in front of the Rolandic fissure, over the second frontal convolution. The dura was opened and an exploring syringe inserted into the ventricle, which was reached an inch from the cerebral surface. By Lister's sinus-forceps a rubber-drain was inserted along the needle as a guide. The drainage was so free that it wet the dressings and ran on the floor, and the patient seemed much relieved. The drainage soon became less free, and on the third day the child died in convulsions. The autopsy showed that the brain had shrunken so much that the end of the tube was lying between the dura and the brain.

Dr. Keen alluded next to the case of Ayers and Hersman, in which, on December 4, 1888, puncture was made over the coronal suture, an inch and a half to the middle line. The operation was repeated on April 28, 1889, by Dr. Hersman. The first operation was followed by the escape of from four to eight ounces of cerebro-spinal fluid and evident improvement. At the second operation no fluid was found in the ventricle, and the child was much improved. The improvement has continued up to May 1890.

Of the 7 cases thus far reported, 2 have recovered and 5 died—a mortality of seventy-one per cent.—which, for a new operation, and for so extremely dangerous a condition, is far from discouraging, especially Mr. Robson's first case.

Dr. Keen then entered into the question of the technique of the operation, and pointed out that it was neither difficult nor dangerous, and that the rules that he had laid down in his former paper [1] had proved to be correct, and that in his judgment the lateral route is the best, except in special instances. From his experience in these three cases, he urges that the puncture be made by a cannula (No. 13, French catheter scale), and that the drainage shall not be done by a tube, but by a sufficient bundle of horse-hairs; and that too much haste shall not be used in draining off the fluid, as such haste may perhaps cost the life of the patient, as in Case II.

Dr. Keen next took up the question of hemorrhage into the ventricles and referred to the following case, reported to him personally by Professor Frederic S. Dennis, of New York. It is the first case in which a clot has ever been removed from the lateral ventricle.

A man, aged thirty-six, was struck on the right side of the head by a falling ladder, but was not rendered unconscious by the blow. An hour after admission into the hospital his left arm became paralyzed, and later, the face and leg also. A diagnosis of cerebral hemorrhage was made, and six hours after the accident he was operated on.

A linear fracture without depression was discovered. Trephining was done over the arm-centre. No epidural and no subdural clot was found, nor was any clot found when the brain tissue was incised. Accordingly, an incision was made directly into the ventricle, and when the retractors were slightly separated a blood-clot about the size of a pullet's egg shot out of the ventricles with force enough to land several feet from the patient's head. Gentle irrigation and drainage, and the ordinary care of the wound. The patient never recovered from the paralysis, became delirious, and died comatose in three days.

The autopsy confirmed the diagnosis, and also that there had been great laceration of the cerebral substance, to which fact death was due. There was no meningitis and no suppuration.

Dr. Keen then narrated four cases of abscess bursting into the lateral ventricle, beginning with the historic case of Detmold, in 1849, and added three other cases by Pancoast, Morehouse, and Morton. All of the cases died, as might be presumed to be the case from so dangerous an accident.

The next series of cases were those due to rupture of the ventricles by compound fracture. Two cases were referred to, one of Massa, the other by Hewitt, in both of which the lateral ventricles were torn primarily, and there was free discharge of cerebro-spinal fluid. Both of these cases recovered.

Of secondary opening of the ventricles he gave seven cases, by Bouchacourt, Berenger, De Carpi, Erichsen, Rodenstein, Cheever, and himself. Strange to say, four of these seven cases recovered.

Five cases of rupture of the lateral ventricles, from simple fracture of the skull, were also referred to; one each related by Thompson, Haywood, Erichsen, and two by Lucas. All of these patients were young children, five years of age and under, and all showing secondary soft swelling under the scalp. The cerebro-spinal fluid was removed either by tapping, or, in one case, by rupture. Of the five cases three recovered. After consideration of the entire subject the following conclusions were reached:

Conclusions.—1. Injuries involving the ventricles, the result of compound fracture or of trephining, and involving great disturbance of the cerebral substance, are not necessarily fatal, for ten of the twenty-six cases here reported have recovered. In these few cases compound fractures and extensive injuries, unless primarily fatal, seem to be less dangerous than rupture of the ventricle from simple fracture. They should be treated antiseptically in precisely the same manner as wounds in other parts of the body, by the establishment of asepsis, drainage, and the usual later treatment. If pus follows, or the cerebro-spinal fluid becomes dammed up, causing symptoms of pressure, incision and free drainage should be resorted to.

2. In cases of simple fracture involving the ventricles experience would seem to indicate that it would be wise not to attempt any operative procedure unless threatening symptoms supervene. If necessary to interfere, I should recommend that the cyst containing cerebro-spinal fluid should be continuously and slowly drained by a small bundle of horse-hairs, rather than by freer evacuation. But, I believe, in the majority of cases constant pressure, and but little active treatment, would meet such symptoms as might arise. Possibly slight pressure would be all the treatment that would be necessary.

3. Abscess of the brain bursting into the lateral ventricle has been thus far uniformly fatal, and demands the promptest treatment possible. The suggestion made for instant bilateral trephining and irrigation of the ventricles can at least do no harm, although the possibility of its doing any good is but slight in so fatal a condition.

4. Hydrocephalus, whether acute or chronic, is usually a fatal disease.

5. Surgical procedures for tapping the ventricles for its relief are easy, and certainly do not *per se* involve great danger.

6. Whether they will cure the disease is as yet not determined. In acute effusions tapping, with or without drainage as may be thought best, will certainly save some lives otherwise doomed to be lost; and in the chronic form, long-continued slow drainage at an early period is at least worthy of a trial, with a reasonable hope of success in a few cases.

7. The methods which I have described for performing the operation, especially by the lateral route, are at least worthy of trial, with a view of determining the value of such surgical procedures.

8. After trephining and tapping of the ventricles, irrigation of the ventricular cavities from side to side is not only possible, but does no harm. In abscesses involving the ventricle, and possibly in other conditions, it may possibly do good. The fluid used for such irrigation should not contain anything which, if retained and absorbed, might do harm. An artificial cerebro-spinal fluid, or a simple boric acid solution, would seem to be the best for such use.

9. Convulsions, due to too rapid withdrawal of the cerebro-spinal fluid, may be checked by re-injection of an artificial cerebro-spinal fluid, or such other innocuous fluid as the circumstances may make available.

10. In either irrigation or injection of the ventricles it is probably desirable that the air should not enter; but such entrance of air does not seem to be productive of mischief.

11. In hemorrhage into the lateral ventricles, at least of a traumatic origin, instant trephining and evacuation of the clot should be done, and in a few cases will probably be followed by a cure, unless the injury of the cerebral tissue is such as to be incompatible with life.

Hospital Nurses.—There are many women entering the profession of nursing whose sense of honor is not high, and whose appreciation of the dignity of labor is not great, but who see in nursing either the means of gaining a livelihood, or a way to escape from the rather dull and petty routine of a single girl's life at home. They like the *éclat* of doing a noble work, and the independence which is essential to it, but are unwilling to do more work than they can help to attain their desire. There are, however, other women who, in taking up nursing, often as a means of livelihood, do so with the highest motives, and who, in rendering themselves independent, have at the same time the great pleasure of helping others in their struggle through life. From this class come all our best matrons, sisters, and nurses, and to them is due the high position nursing holds as a profession for women. —*Murray's Magazine.*

SOME CASES OF JOINT TUBERCULOSIS.[1]

By NATHAN JACOBSON, M.D.,

PROFESSOR OF CLINICAL SURGERY IN THE COLLEGE OF MEDICINE, SYRACUSE UNIVERSITY.

WHILE not intending to present an exhaustive paper upon tuberculosis of the joints, it may be wise to remind you of certain anatomical and pathological data, that I may the better emphasize certain clinical manifestations to which I propose to invite your attention.

The pathology of surgical tuberculosis has been entirely rewritten during the last decade and a half. All joints are subject to a variety of inflammatory disturbances. Few observers, however, are ready to follow Max Shüller, who states, in a very elaborate article in Eulenburg's "Real-Encyclopädie," that most acute and chronic joint inflammations, even though apparently simple in character, are awakened by the introduction of microbes or their ptomaïnes, which have entered the blood from inflamed or suppurating sites in the skin, connective tissues, bones, and mucous membranes of various organs, especially the tonsils, nose, lungs, intestines, and urinary tract.

Tubercular disease of a joint begins either in its synovial lining or in the spongy portion of a bone entering into its formation. The physiological connection between the joint cavities and the lymphatic system is most intimate. The peculiar anatomical construction of spongy bone, which is so very vascular, leads to a slowing of the blood-current, and favors, therefore, the heaping up of infectious matter brought there in the blood.

Pathological studies and experiments have shown that small thrombi form in the spongy bone, or slight hemorrhages occur upon the synovial membrane. Tissue necrosis results, and the foci for inflammatory disturbances are at hand.

The localization of the inflammatory process at a given joint is explained not only by its individual anatomical peculiarities, but also by the active intervention of external excitants, such as traumatism, exposure, and excessive use, which precipitate the disturbance by calling an unusual amount of blood to the parts, occasioning rupture of the vessels and the discharge of blood laden with disease-producing germs.

In themselves contusions, overstrains, and exposure cannot produce tubercular joint inflammation, except there be present at the same time the specific tubercular bacillus. This explains why, after a slight injury, the inflammation assumes a varying type in different cases.

In 206 cases collected by Shüller, 54, or twenty-six per cent., were tubercular in character. Of all the joints the knee was the most frequently involved, the disease being localized here in thirty-five per cent. of the cases. In the hip it occurred in fifteen per cent.; the elbow, twelve per cent.; the ankle, eleven per cent., and in the shoulder least of all, only four per cent.

Tubercular disease begins much more frequently in the bone than in the synovial membrane. There seems to be no single, constant form of pathological change even in these two classes of cases. The synovial membrane, while presenting the appearances which correspond to those of tuberculosis in other parts, exhibits also great variation in detail in different cases.

Ordinarily it is studded with tubercles separated, or in groups of varying size; surrounding them the tissues are in a state of inflammatory disintegration or vascular granulation. The synovial membrane may become so altered that it closely resembles plush studded with flat, pale-gray granulations. In other cases tubercular tumors of the size of a dove's egg may develop. But, however altered, it looses its identity as a synovial membrane and becomes the ensheathing capsule of a cavity containing either a serous fluid or caseous pus.

The tubercles exhibit a tendency, as elsewhere, to caseous degeneration. In the spongy bone the tubercles congregate in the same manner, become caseous, soften the bone structure, occasion its death—when caries is said to exist. These little tubercular pockets in the bone are also lined with a characteristic tubercular membrane.

While we meet with one group of cases where suppuration occurs and cold abscesses are formed, we encounter another which the text-books formerly designated "tumor albus," in which the pathologist simply finds tubercular granulation tissue.

The abscesses have either an articular or peri-articular origin. In the former, rupture of the joint-capsule has occurred, and we have the "Senkungs-abscess" of the Germans. When there is *no* communication with the joint, the suppuration may be due to decomposing blood-clots, glandular degeneration, the existence of phlegmon, or periosteal inflammation, with an attempt on the part of nature to expel the carious fragments of bone.

Allowed to open spontaneously, the discharge continues through fistulæ thus created. If these fistulæ are examined there will be found the characteristic tubercular membrane commonly called a pyogenic membrane.

The progress of joint tuberculosis is usually slow. Exceptionally it may be rapid, as when there is a sudden discharge of cheesy bone foci into the joint, or a rapid cheesy disintegration of the synovial membrane, or where there is sharp septic infection introduced from without through existing fistulæ.

The disease progressing produces local destruction. It attacks the cartilaginous covering of the articular surfaces of the bones, and even the osseous framework of the joints cannot withstand its pernicious invasion. Sooner or later constitutional infection is manifest. The lungs, brain, and other organs exhibit tubercular disease.

Though search has been made in my cases, the microscopic slides have not always, to say the least, exhibited a rich field of bacilli. When present, these are not usually found in the granulations, but in the structures surrounding the cheesy foci and in the fistulæ.

A few words as to the clinical picture joint tuberculosis presents. Having reached the final stage of caseation and suppuration, with abscess formation, the diagnosis is easy, but unfortunately the mischief done has been so extensive that recovery then no longer means restoration of integrity.

For obvious reasons, an early diagnosis is all-important. All acute inflammatory appearances are now absent. The skin is pale, and may present even an ivory whiteness and a dull lustre. Later the color may change to a pale-blue or bluish-red. The temperature is normal, but when caseation occurs it may be somewhat elevated, but never to the degree it is in an acute inflammation.

The outline of the joint is lost as the parts slowly exhibit the presence of a half-œdematous, half-chronic inflammatory infiltration extending even beyond the limits of the joint-capsule, and fluid within the joint-cavity can be recognized. The contour of the joint is further changed by the early wasting of the muscles about the joint. The position of the joint and the limb is altered by the contracture and the rigidity of the muscles. These changes in position, occurring at a very early period, are often the most suggestive manifestations present. Measurement of the joint, while indicating the change in shape, does not furnish any help in reaching a diagnosis.

Palpation may disclose changes in the capsule and the peri-articular structures. Fluctuation can be discovered in the position which will render the fluid most prominent, yet over-distention of the capsule is undesirable. It is more apparent rather where the fluid is liquid than where it is abundant.

If the pus be thick, or clotted blood be present, its recognition is difficult. To discriminate between elasticity and fluctuation when there is but little fluid, and where the synovial membrane is swollen and much granulation tissue is present, requires no little dexterity.

The functional activity of the joint is greatly impaired. The early disturbance of function with moderate objective

[1] Read at the meeting of the Central New York Medical Association, held at Rochester, N. Y., June 10, 1890.

changes in a joint is very suggestive of tubercular inflammation. The weakness of the muscles is accompanied by marked diminution in their electrical reaction.

The degree of pain experienced varies. It is most marked in the early period when the disease is of bone origin. It is usually present after use or palpation.

The obstinacy of a slowly developing joint inflammation, the persistence of hydrops, refusing to yield under intelligent treatment, is suspicious of tuberculosis.

Sooner or later the tubercles undergo caseation, and suppuration occurs. Seen at this time, when abscesses have burst or have been opened, it becomes necessary to determine whether the pus is of articular or peri-articular origin. The condition of the joint, the localization of the swelling, the presence of pain or crepitation on motion, the mobility of the joint, must be studied, and search for the other usual signs of suppuration be made.

A probe carried into the fistulæ may furnish useful information. The character of the pus is to be noted. If mucilaginous, it is probably mixed with synovia; although if the synovial membrane be converted into a granulating surface this peculiarity will be absent. Coming from a bone cavity, pus may contain fine, sandy, bone particles. Pressure upon the joint-capsule may force pus out, if it be contained within the articular cavity.

Joint disintegration now follows. Destruction of the ligaments, cartilages, and bone occurs, and luxation of the joint is very easily produced.

At a very early period there is loss of appetite, disturbance of nutrition, pallor, restless sleep. With cheesy degeneration an evening rise of temperature appears. Still later, there is a characteristic hectic, with profuse night-sweats and perhaps albuminuria. While it is wise at all periods of a tubercular joint disease to examine the patient carefully for any signs of organic tuberculosis, it is particularly at this late stage that such evidence is furnished.

Permit me now to refer to a few cases.

Case I. *Tubercular Inflammation of the Hip-joint, with Apparent Recovery, followed Fourteen Months Later by a Fatal Tubercular Meningitis.*—This patient was under the care of Dr. F. W. Sears, of Syracuse, whose notes I am permitted to use.

F. H——, aged nineteen months. Father sixty years of age, mother twenty eight. When the child was eight months of age the family moved to Syracuse. At once the child, previously healthy, began to fail. When sixteen months of age sustained a fall. One month later manifested the usual symptoms of hip-joint disease, the joint being exquisitely sensitive, the muscles about it extremely rigid. Tilting of the pelvis, as the knee is brought to the table, while the child lies in the recumbent posture, and characteristic position of the limb. Extension was applied and the child kept on its back. Immediate relief came. In one month the signs of joint inflammation had disappeared. The extension was continued but nine weeks, as the parents objected to its further use. There never was any recurrence of joint symptoms. Fourteen months later the doctor was again called to the child. He had been ailing for a few weeks. There was now prostration, a dull, listless expression, pain in the head, and moderate rise of temperature; mucous and crepitant râles over a large area of both lungs. The child had spells of twitching and staring. Several days later drooping of the left upper lid, and paralysis of the left arm and leg appeared. The condition grew steadily worse, and the child died after lying in a semicomatose condition for two days. No autopsy was allowed, but the death very evidently was from tubercular meningitis.

It is not unusual for joint tuberculosis to reach a state of quiescence. In fact, it is quite the rule for it to exhibit treachery; for the symptoms to disappear and the patient to be considered cured, only to meet with disappointment as time brings recurrence. But the continued absence of the joint symptoms, to be followed by an outbreak of meningitis is, I believe, extremely rare.

Case II. *Caries of the Wrist, followed by Pulmonary Tuberculosis; Death.*—March 18, 1888, I was requested by Dr. D. H. Murray, of Syracuse, to see J. N——, aged sixty-five, who was dying of pulmonary tuberculosis. A brother and sister had died of consumption, as had also one of his own sons. Five years before he was seized with pain in his right middle-finger, which recurred at intervals for a year, when it extended to the wrist. Medical treatment failed to relieve him. Eighteen months later the wrist began to swell and the pain increased in severity, extending now to his elbow. The muscles of the forearm wasted and lost their tone, fluctuation appeared at the wrist-joint, while the elbow became partially anchylosed. The forearm was fixed in the pronated position. At the time that these changes in the wrist reached their height, he developed a cough. He lost greatly in weight and had an evening rise of temperature, and night-sweats.

On December 23, 1887, he sustained a fracture of the humerus. Union was established in seven weeks. But from this time on the patient steadily grew worse. When seen by me, pulmonary tuberculosis existed in both lungs, though more advanced in the right. The right wrist was one inch larger in circumference than its fellow; there was fluctuation in the wrist; preternatural mobility of the lower end of the ulna, indicating destruction of the articular ligaments, and marked grating as the bones of the forearm were rubbed against the carpus. The forearm measured, just above the wrist, $4\frac{3}{4}$ inches; below the elbow, $5\frac{3}{4}$; above the elbow the arm had a circumference of $5\frac{1}{2}$ inches. Each of these measurements was one inch less than that of the left arm and forearm at a corresponding point. The patient was bed-ridden, had scarcely strength to raise himself. He expectorated very profusely a foul-smelling, greenish-yellow sputum, which microscopically presented large numbers of bacilli. He grew steadily weaker and died three weeks later. The wrist was opened post mortem, and found to contain cheesy pus. The bones were carious, the ulna particularly so. Dr. F. W. Sears prepared and examined the pus. Bacilli were found. The slides were exhibited at a meeting of the Onondaga County Medical Society. Here we have another instance of the possibility of organic infection without extensive local destruction. Pulmonary infection evidently began with caseation of the tubercles in the wrist. Early resection would probably have averted the pulmonary disease.

Case III. *Tubercular Synovitis of the Hip-joint; Apparent Recovery; Recurrence after Traumatism; Bone Invasion accompanied by Pulmonary Disease; Resection of Hip-joint.*—P. L——, when first seen, April 24, 1886, in consultation with Dr. Maas, was twelve years of age. The maternal grandmother died of tuberculosis. His mother is pale, thin, and ailing constantly. One brother had hydrocephalus; another since has had chronic meningitis. He had been kicked in the hip during a scuffle, and five weeks later exhibited signs of hip-joint effusion. Under extension by pulley and weight at night, the auto-extension, during the day, and by adding a heavy sole to the shoe worn on the sound limb, he seemed to make a satisfactory recovery. At any rate he remained quite well for nearly a year.

On June 27, 1887, I was again called to see him, by the attending physician. The symptoms had returned with increased violence. The pain in the hip, especially at night, was intense. Extension no longer relieved him. The glands of the groin were enlarged. The trochanter major was very prominent and seemed increased in size. There was hectic fever, night-sweats, and great emaciation. The lungs were dull at both apices; in the infra-scapular region of the left side was an area, the size of a child's fist, which was flat. At these points the breathing was cog-wheeled and exaggerated. At the left apex there were crepitant râles; at the right, additionally, subcrepitant, and also sonorous and sibilant. At the base there was bronchial breathing and an increased number of râles.

Resection of the hip-joint was performed. Upon opening the joint a large quantity of curdled pus was discharged. The head and neck of the femur were removed with chain-saw. The synovial membrane, covered with rich fungous granulations, was cut away. The acetabulum presented a carious site at its centre. This was scraped with Volkmann's spoon. The cavity was thoroughly irrigated with sublimate solution 1 to 2,000, packed with iodoform gauze, antiseptically dressed, the boy put to bed, and extension applied.

Slight febrile reaction occurred. Five days after operation he had on three occasions slight pulmonary hemorrhage. There was no other untoward symptom. The wound healed kindly. The general condition improved under hypophosphites and cod-liver oil. Extension was continued eight weeks. The lungs cleared up. Dr. H. L. Elsner, of Syracuse, who assisted me at the operation and who examined the boy's lungs then, finding the condition as above stated, re-examined him with me September 12, 1887, twelve weeks later, when neither of us were able to detect the existence of any pulmonary disease. The pus and portions removed were examined for bacilli, but none were found.

I present to you four plates which exhibit admirably the condition found. They exhibit the synovial membrane with its rich granulations. The fine miliary granulations could not be here portrayed, but were readily demonstrated as the membrane tacked upon a black background, as suggested by Volkmann.

At the site of attachment of the ligamentum teres destructive ostitis is seen to have occurred. The cartilage of incrustation, raised at its circumference from the bone, and changed in color from contact with the joint contents, is shown. The transverse section represents accurately the depth of bone invasion.

Despite the fact that the boy, contrary to all advice, began to work in a cigar factory after his recovery, and continued steadily in employ there until the present spring, he has never manifested any further pulmonary tuberculosis. He has been able to get about easily with the aid of a crutch; has had good motion of the hip. During February of the present year, however, the wound reopened. Slight febrile disturbance appeared, and he was admitted to St. Joseph's Hospital, in Syracuse, March 15, 1890.

I found a sinus leading down to the upper end of the femur. Five inches below it there was an abscess. Under ether I opened up the fistulous tract freely; scraped away its tubercular lining; curetted the bone, removing some carious particles; made a counter-opening into the abscess cavity and gave vent to some cheesy pus. Here also the characteristic membrane was found and removed with the spoon. The whole was irrigated with 1 to 5,000 corrosive sublimate solution and a drainage tube placed. In six days this was removed. Gelatine bougies containing five grains of iodoform were used every alternate day, preceded by irrigation. In this manner recovery took place; the patient being discharged from the hospital May 16, 1890.

This case illustrates nicely the course of tubercular joint inflammation beginning as a synovitis. It emphasizes the danger of recurrence after apparent cure, and the extension of the disease, then, to the firmer structures of the joint. The relation of pulmonary tuberculosis to that of the joint is clearly shown by its disappearance after relief of the surgical affection. Operative interference in these cases is not only justifiable, but positively indicated.

While, as Eulenburg says, joint resection is by no means to be regarded as a panacea, there is no doubt that the prognosis is much better than is generally believed. In 1880, König, in a paper read before the German Surgical Congress, stated that with each successive year after resection the death-rate from tuberculosis progressively increases. Schmid-Monnard contributes some interesting statistics to the *Centralblatt für Chirurgie*, December 28, 1889, in which it is shown that where death follows from tubercular disease, in sixty-four per cent. of the cases this occurs during the first year, and that from this time on the outlook becomes more favorable. Where at the end of two and a quarter years after operation there was no reappearance of tuberculosis, local or general, the death-rate was reduced to four per cent. Therefore it can be given out as a rule, that patients reaching the period of two and a quarter to two and a half years, *post operationem*, without tubercular manifestations, may be considered permanently cured.

Case IV. *Tubercular Ostitis of the Hip, with Perforation of the Joint-capsule; Cold Abscess; Fistula; Resection.*—H. H——, aged five years and six months. Admitted to St. Joseph's Hospital, Syracuse, March 19, 1889. His father is of consumptive family. Two years previous had pain in left knee, cried out in his sleep, limped on awakening in the morning. Hip-joint disease was diagnosticated. Buck's extension applied, and continued for a few weeks. But the boy's general health failed so rapidly that Sayre's splint was applied, that he might be out of doors, and was worn until August 18, 1888. No improvement occurring, extension was reapplied. Soon after, a cold abscess was discovered on the inner side of the thigh, which was allowed to open spontaneously. One month prior to admission into the hospital he had pharyngeal diphtheria. When admitted, he was in a wretchedly exhausted condition, both from the long-continued suppuration and his recent illness. There was a sinus on the inner side of the thigh at the upper third, a cold abscess on the outer side, and the signs of hip-joint disease in the third stage. March 25, 1889, I resected the hip. In the joint cavity there was cheesy pus. The head of the femur had so completely melted away under the destructive ostitis that a mere knob remained at the end of the neck. The plates which I present to you will convey some idea of the condition found. Hemorrhage slight.

The acetabulum was also carious, so that it was necessary to remove a portion of its entire thickness. The shaft of the femur was freed of its marrow with a Volkmann's spoon. The abscess on the outer aspect of the thigh was opened, vent given to the cheesy pus it contained, and the tubercular membrane lining it removed by curetting. The sinus on the inner side was treated in the same way. Powdered iodoform dusted into the different cavities. Each packed with iodoform gauze. Extension with light weight applied. For the first three days the little fellow was more dead than alive. He was so very weak that he could hardly be fed. Under careful stimulation and tonics his strength gradually came up. There was little febrile disturbance. The wound did well, but had not entirely healed when his parents insisted upon removing him to his home, June 4, 1889, ten weeks after operation. I did not see him again until June 4, 1890, just one year after leaving the hospital, when I induced a friend of the family to bring him to my office for examination. I found him in excellent general health; he gets around in a very lively way with the aid of his crutch, playing out of doors constantly; his color is good, and he has no cough. The limb is shortened 2½ inches; has a tendency to rotate inward, which he readily overcomes. The thigh measures 8¾ inches in circumference, as against 10½ of the left, and the calf of the right leg is 1 inch less than its fellow. The pelvis is tilted downward on the right side. The wound was still unhealed; for out of it projected a piece of necrosed bone which had presented at this site for several months. I had no difficulty in turning the sequestrum out of its bed without the aid even of an instrument. I present the specimen to you. The granulations attached to the bone have been searched for tubercular bacilli, but none have been discovered.

The recovery of this boy, when at the time of operation his condition was as unpromising as it could well be—the physicians assisting being indeed fearful that he might not live through the operation—encourages us in the belief that even desperate cases are not beyond surgical

aid. Yet the history of this case also clearly shows the necessity of early operative interference, especially where the disease is primarily of bone origin.

CASE V. *Tuberculosis of the Shoulder joint, of Bone Origin; Cold Abscess; Operation; Recovery.*—G. H——, aged three and one-half years when seen by me, December 1, 1884. Both parents well. Father's mother died of consumption; mother's father died of chronic diarrhœa; one cousin of the mother died of consumption; a cousin of the little patient has Pott's disease of the spine.

Without apparent cause, persistent pain appeared in the left shoulder. Some months later the joint became swollen, and movement of the arm was restricted upward and backward. At the first visit the circumference of the joint perpendicularly around the axilla was one inch greater than its fellow. Inunction with iodide of ammonium ointment was prescribed, and as there was some wasting of the deltoid and other muscles, the faradic current was applied. This was continued without benefit for three months.

March 13, 1885, first indication of abscess, which I opened April 11, 1885. Pus was yellow and creamy at the time of incision, but changed in the course of two months, becoming thin and watery. The remaining fistula failed to close until August 1, 1885, and then only after the tubercular membrane lining it had been removed with Volkmann's spoon, and the cavity treated persistently with iodoform.

Even then it did not remain healed, but soon reopened; the pain and restricted motion continued; the probe led to carious bone. January 9, 1886, I cut down upon the humerus, the incision extending from the anatomical to below the surgical neck. I found extensive caries, which was thoroughly removed with the spoon. Resection, of course, was not thought of, as it would necessarily interfere with the growth of the arm. It was found, however, when all diseased cartilaginous and osseous structures had been removed, that an opening through the entire thickness of the bone had been made, large enough to permit the passage of my index-finger.

Iodoform dressing followed. Repair was slow. A fistulous tract remained until August, 1886, which finally healed with the use of the iodoform gelatine bougies. The girl made an excellent recovery and has continued uninterruptedly in the enjoyment of health. She is now nine years of age.

Examination of the arm and shoulder, June 5, 1890, resulted as follows: Left scapula somewhat depressed. Supra- and infra-spinatus muscles slightly atrophied; head of the humerus thickened, especially on its anterior aspect. Circumference of the left arm, at highest point possible, $6\frac{3}{8}$ inches; right, at a corresponding point, $7\frac{5}{8}$ inches. Length of the left arm from acromial extremity of clavicle to outer condyle, 7, to inner, $7\frac{1}{2}$; of the right, $8\frac{1}{2}$ to 9 inches to corresponding points. There is therefore shortening of $1\frac{1}{2}$ inch of the humerus. The girl can raise the hand to her head, can carry it to the small of her back, and with elbow against the chest touch the opposite shoulder. Evidently, therefore, she has a serviceable arm. The case, however, shows that even conservative operative measures in the neighborhood of epiphyseal cartilage does affect the growth of long bones in a very decided manner.

These cases, selected from those coming under my observation, present many of the salient points we encounter in the study of joint tuberculosis.

But one thought more, and then I have finished. While I have seen primary pulmonary and meningeal tuberculosis awaken various forms of secondary tubercular disease, it has but once occurred in my practice that tuberculosis of the joints has appeared as the secondary affection. I believe that this must be rare. And yet, with the intimate relations existing between the vascular and lymphatic systems and the articulations, this fact cannot but be striking.

The necessity of the early recognition of joint tuberculosis is now universally conceded, and the importance of early operative treatment fully appreciated.

Clinical Department.

TETANUS AND RABIES.

BY STEWART PATON, M.D.,

NEW YORK.

THE clinical reports of cases of tetanus and rabies so often emphasize the similarity of the symptoms of these two maladies that the actual differences of even typical cases are frequently forgotten. Owing to the rarity in man of genuine rabies the opportunities are few for comparing the development and progress of these diseases. This has been considered sufficient excuse for publishing in brief the notes on a case of traumatic tetanus and one of rabies which recently came under observation.

The Case of Tetanus.—Thomas W——, aged sixteen, a laborer, gave the following history: On March 9th received a slight scalp wound from a falling wrench. He was unconscious for about five minutes, but after a short rest he was able to continue his work. The wound was washed and dressed at home. The day following the patient was in his ordinary health and experienced no trouble from the wound. On March 26th he began to have pains in his teeth and all along his spinal column. There were marked spasms of the spinal muscles, with considerable opisthotonos, on March 27th, the eighteenth day after the receipt of injury. On April 1st he applied for admission to the hospital. His physical condition on admission was the following: He was emaciated, anæmic, muscular development poor. Slight trismus, no affection of muscles of deglutition or of respiration. Lungs normal; heart strong, rapid; loud systolic murmur at apex; other viscera apparently normal. There were marked tonic spasms with paroxysmal exacerbations of the abdominal and spinal muscles. These were exaggerated by any form of peripheral irritation, and were accompanied with great pain. The muscles of the arms and legs were only slightly affected. The mind was perfectly clear, and the patient seemed to appreciate his condition. He was immediately put to bed, and all exciting causes, such as loud noises, bright lights, and draughts of air were, as far as possible, removed. The course of the disease was subacute. The temperature curve was irregular, ranging between 102° to 106° F. The therapeutics of the cases were interesting. Urethane in doses of gr. lx. made the patient drowsy, and the first twelve hours lessened the severity of the spasms. The combination of bromide of potash and chloral, even after the addition of active cardiac stimulants, depressed the heart's action to such an extent that its administration had to be suspended. Physostigma was then tried. Squibb's extract was given hypodermically, gr. $\frac{1}{4}$ every two hours, while at the same time cardiac stimulants were exhibited. The physostigma modified the spasms, but the pulse became rapid and feeble, and the sphygmograph showed an increase of arterial tension. The pupils were slightly contracted. When even the heart became so weak that it was thought necessary to suspend the administration of physostigma, the spasms seemed constantly increasing in force and frequency.

The patient died on the eighth day after admission to the hospital. Even when the trismus and opisthotonos were most marked the patient's mind remained perfectly clear, and at no time was he maniacal.

The Case of Rabies.—Edmund C——, aged thirty, a laborer, and a native of Canada. On May 11th he was bitten on the left wrist by a small terrier. The dog was killed out of pure revenge, but not before it had bitten several dogs, which subsequently developed rabies. The wound was a slight one and healed rapidly. The patient was not of a neurotic temperament and he never thought of the possibility of hydrophobia developing. On the evening of June 5th a sharp, needle-like pain developed in the cicatrix, and radiated up the arm as far as the

shoulder. On the evening of July 6th the patient experienced considerable difficulty in swallowing. Both these symptoms continuing on the 7th, the patient consulted a physician, who advised him to come to New York for treatment. About 1 A.M. on July 9th, the patient, accompanied by his physician, walked into the reception-office of the hospital, and was immediately sent to one of the wards. The patient was a very muscular man of about medium height. His skin was covered with a cold, clammy sweat. Both eyes were suffused, and there was slight internal strabismus and protrusion of the eyes, which had developed about twelve hours prior to his admission to the hospital. The speech and respiration were both jerky, but as yet the mental faculties were unaffected, so the patient was able to answer the questions that were asked him. Salivation was marked, and the patient was continually hawking up and spitting in all directions a viscid saliva. There was no facial paralysis or trismus, but every attempt at swallowing was accompanied by such marked spasms of the muscles of deglutition that the patient became frantically delirious in his attempt to quench his excessive thirst. A glass containing water given to the patient would be resolutely carried to his lips, but as soon as a little of the fluid entered his mouth it was forcibly ejected and the rest spilt. At first there was no aversion at the sight of fluids, but later this was a marked symptom.

The muscular spasms, tonic in character, were accompanied by a terrible feeling of oppression and fear of impending death. The heart was rapid, feeble, and somewhat irregular both in form and rhythm. The pulse was high tension. Temperature 102° F. The patient was immediately put to bed and all forms of peripheral irritation were as far as possible removed. Urethane in doses of gr. lx. had no effect on the spasms, and the same was true of bromide of potash and chloral. Physostigma hypodermically slightly modified the intensity of the spasms, but depressed the heart to such an extent that its administration had to be suspended. The hypodermic use of Magendie, ♏xx. at a time, was also ineffectual, and finally, as the patient became maniacal it was necessary to administer chloroform. There was no trismus or opisthotonos. The muscles involved were those of the pharynx, thorax, and the diaphragm; the involvement of the latter apparently accounting for the very acute epigastric pain, which was paroxysmal in character and synchronous with the spasms of the other muscles. For one hour before death the patient was in a condition of collapse, and gave evidence of the profound exhaustion of the nerve-centres. The surface was cold, and there was marked muscular relaxation. The radial pulse was imperceptible, and the heart was beating so rapidly and feebly that its impulses could not be counted. Death occurred fifteen hours after the patient was admitted to the hospital, and on the fourth day after the development of the first symptom. Fifteen minutes after death the rectal temperature was 107.2° F. The autopsy revealed practically nothing abnormal except a few small hemorrhagic foci in the floor of the fourth ventricle.

The typical character of both cases, and the absence of any aberrant feature which might throw doubt upon their genuineness added considerably to their interest. The trismus, opisthotonos, and almost complete absence of delirium, were the salient features in the case of tetanus; while the marked salivation, embarrassed respiration, difficulty in deglutition, unaccompanied by trismus, and the maniacal delirium, were eminently diagnostic in the case of rabies.

Although medication did not materially affect the course of either malady, the partial control of the spasms through the agency of urethane and physostigmine no doubt alleviated the patient's suffering in the case of tetanus, and certainly demonstrated that the treatment of tetanus by drugs after the development of the initial symptoms is not as hopeless as is the treatment of rabies.

BELLEVUE HOSPITAL.

A CASE OF SPLENIC DISEASE.

BY A. S. ASHTON, M.D.,

PIQUA, O.

I DESIRE to give a brief account of a peculiar and (to me) interesting case that occurred recently in my practice.

In the latter part of June, a little girl, five years of age, under high febrile action and some irritation of the bowels, had an attack of convulsions. This attack soon passed off, no other paroxysm following it.

Convalescence seemed perfect, saving a jaundiced condition of the skin.

Three weeks thereafter, an eruption, similar to that in measles, yet wanting the other symptoms of the latter disease, appeared over the whole body. This continued only a few days, and was of so mild a character as not to interfere materially with her childish sports; the skin, however, retaining a slight icteroid hue.

August 15th.—Again visited the little patient, who had a slight febrile action following a chill that seemed to call for little medication.

August 16th, A.M.—Condition about the same.

At 9 P.M., of the same day, she awoke from a two-hours' sleep with increased temperature and restlessness that continued throughout the whole night.

August 17th, A.M.—The patient was suffering from distressing pains over the whole body, and stiffness of the joints. To so great a degree was the soreness, that it was well-nigh impossible for her to move the limbs on the left side.

At this visit the temperature was 104⅘° F., pulse 140; pyrexia continued throughout the night.

August 18th, A.M.—Crisis occurred, with profuse perspiration and a subsidence of all the acute symptoms. For ten hours thereafter the little patient rested quite comfortably; complaining chiefly of pain in the bowels.

About noon a dark, congested spot, three by three inches, was noticed above the wing of the left ilium, overlying the spleen. For several hours the spot was not observed to increase any, but during that night it spread rapidly.

August 19th, 9 A.M.—The discloration extended anteroposteriorly, from the median line of the rectus muscle to the vertebral column, and from the junction of the middle and upper third of the thigh to a line corresponding to the lower border of the fifth rib. There was also a number of small, livid spots on the lower extremities. There were none on the right side until just before death, when a purple spot or stain appeared over the right ilium, three by four inches in extent. Respiration now became hurried, pulse very frequent and feeble, extremities cold, extreme thirst and jactitation followed, by death, which occurred at 2 P.M. Throughout the whole sickness—it is worthy of note—there seemed to be no impairment of the intellectual faculties.

Autopsy, twenty-four hours after death: Rigor mortis well marked. The area of discoloration had not increased, but the color, which before death was a dark plum or purple, had faded to a bright red. The adipose tissue underlying the dark patches was infiltrated, presenting the appearance of complete stasis of blood in the cellular tissue. The spleen was soft and completely disorganized, and enlarged to twice its usual size. All the other organs in the abdominal cavity were normal. This is the clinical history of the case. If I have been too minute in the details, it is only that all errors in judgment may be avoided.

If any brother practitioner has met with a similar case, I request him to state the diagnosis and treatment of the same, and lastly, which is no less singular, what was the mode of death in this apparently anomalous attack?

A Good Liniment for Burns, according to the *Union Médicale*, is composed as follows: Salol, 1.0; Ol. olivæ Aq. calcis, āā 70.0.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, September 20, 1890.

BETTER TRAINING—BETTER SURGEONS.

MR. TAIT, of Birmingham, is both an active surgeon and an active controversialist. One rarely takes up any of the leading English medical journals without finding evidence of some little dispute which he happens to have on hand. He manifests a broad catholicity of disposition in his strictures, for he not only attacks his own countrymen, but is engagingly lavish in his criticisms of dead and alive Americans, Germans, and Frenchmen.

The latest and not the least trenchant display of his fault-finding faculties is made in his "Address on Surgery," delivered at the recent meeting of the British Medical Association.

His first frank confession is to the following effect: That we have made mistakes, that we have had to confess that our favorite theories and some of our best established practices in one generation have become the flogging-posts of the next, is but to confess that we are human. Nothing is human if it can have no progress, and progress is impossible in all human affairs without error. But with all our shortcomings there is none unwise enough to avoid the counsel and help we can give him when the inevitable hour of trouble comes for his turn. The scoffer may be what he likes when he is well, but when the abscess pains or the tumor threatens, his tastes speedily become monastic. Humanity has, on the whole, a complete confidence in us, not that we are perfect, but as far as we are so approached we honestly do the best we can.

He thinks that we practise a mere handicraft, but the philosopher who asserts that liberal education will spoil the future craftsman is a mere bookworm, without a true knowledge of human powers. Now a surgical craftsman must be a trained gentleman, accustomed by a classical education to use his native tongue with ease and fluency and without confusion. He must have the fundamental principles of reasoning and of business habits instilled into him by such mathematical training as will be involved in his being able to pass some one of the ordinary examinations now insisted upon by all the licensing bodies. If he can spare the time and money to become a graduate in arts, so much the better.

Tait says, with much show of reason, that our successors ought to be spared that senseless grind at useless details of anatomy with which our own young memories were burdened—details which one can remember only by a demoralizing system of catch-words—details which the student prepares himself to forget the moment the necessity of examinations is over.

Still more strenuously does he insist that our student be altogether relieved from that senseless system of biological training which has set in as a fashion at Cambridge, at Oxford, and at Edinburgh. How angry such students must feel when they come to deal with human patients and human disease, that all these nonsensical details are of no use to them—not even for the purpose of general training—when they find, in truth, that the time occupied in mastering such subjects has been absolutely thrown away.

We, too, are of the opinion that medical students ought to stick to medicine. There is surely enough of it to give them occupation for a few years.

Tait reminds us that in the old days it was charged against the corporations that they turned out a large number of ill-educated empirical practitioners who knew nothing but their patients. Now the tendency is to turn out a still larger number, a very much larger number of scientific young tyros who know neither patients nor their diseases till they have gone through a second pupilage extending for years after they have left their university. This second pupilage lies in the rough school of experience, and in its second training they will be found deliberately and at once to throw overboard at least two-thirds of what they have learned in the first. The young student should be put at the earliest possible time in contact with his material. Tait votes cordially with those who demand the restoration of the apprenticeship system in such fashion as modern requirements indicate. It is of course no longer to be a seven years' slavery in mixing pills and spreading plasters, for the modern manufacturing chemist does all that for us now; but it should be a period of at least two years spent in learning how to deal with patients, how to divine their peculiarities, and in learning how to avoid making an ass of himself in the sick room, as the modern, newly fledged, qualified assistant is certain to do for the first few years of his second pupilage, in spite of his biological lore.

The road to success in the practice of our art lies not only in knowing how to deal with disease, but how to deal with men and women while they suffer from it. Our biological practitioners have no experience of either of these lines of research, and they therefore fail miserably.

He says a pleasant little thing in favor of medical bodies, when he asserts that they are deaf to our appeals, because their rulers no more understand the requirements of the general practitioner than they understand the Confucian system of philosophy.

He maintains that a training in practical mechanics is far more necessary for a man who has to operate upon his fellow-human beings than is a training in anatomy.

As a matter of fact, at present in medical education the cart is being uniformly put before the horse. Impressions in youth are far better and more lastingly conveyed by the eye than by any other sense. Words referring to clinical systems and to physical diagnosis, which are now a mere shibboleth to the student, would, under better arrangement, possess a living interest; for what is used merely as dead rote for the purpose of passing examinations would

survive for his lifetime as the guiding principles of his practice.

The revolution wrought in surgery by the introduction of anæsthesia is eloquently set forth. Tait speaks of the vulgar theatrical display that was formerly (?) made of operations. He aptly remarks that it often makes him sad to hear of the anxiety professed by many of his profession to "see" some great surgeon perform some big operation —an operation which they themselves would never entertain a wish to undertake. Such performances ought to take place only in the utmost privacy and be witnessed only by such as can really be benefited by observing them, that is, men who wish to engage in operating practice and are likely to have fields in which to fulfil their wishes.

He is quite severe on theories. Surgical theories never lead to anything. Not even the great antiseptic theory has led to any tangible result beyond what every housewife knew before its day, namely, that dead, moist, organic matter will decompose if some agent or other gets to it. We know now the exact nature of this agent, but this is a new fact, not a new theory. The theorists forget that living tissue will not decompose under the access of the same influences—influences, indeed, which surround us at every moment of life, and pass by harmlessly. Now the theorists take a lingering farewell of their lost darling by saying, "Well, at any rate, it taught us cleanliness." As a matter of fact, the very reverse of this is true, for it was the arguments of those who opposed the antiseptic theory which demonstrated the successful cleanliness. The last phase of this discussion is the antiseptic accoucheur, who pleasingly fancies that both his theory and his practice are new, whereas in matter of fact Semelweiss literally died for them nearly thirty years ago. Semelweiss had no theory, he simply stated the fact that puerperal women in Vienna were poisoned by dirt. "Wash your hands," he cried, "and the women will not die," and his colleagues ruined him for his frankness. But he persuaded the world he was right. Simpson took up the fight with his accustomed vigor, and carried it through, and now, forsooth, we hear of the antiseptic theory as applied to midwifery as a new thing.

What is wanted for the improvement of our surgical results is not any more theories, but better work and better systems of working, preceded by better systems of training. We forget that an art like surgery cannot be acquired by passing examinations.

Tait also has his little fling at general practice. No sooner is a new drug placed on the market than everybody rushes to try it. At first all is well, and "rubbishin" is good for everything. Then come a few isolated hints about the "toxic effects of 'rubbishin,'" and finally "rubbishin" gets dropped altogether, and we hear no more about it. It is positively awful to think of what some of these new drugs—say chloral, for instance—may have done before they got settled. For the mischief that is done in this way the public is largely to blame, if indeed it is not wholly to blame; they like the idea of a new discovery, especially the upper classes, and Tait is told by men practising near the dwellings of the princes of the land, and at fashionable watering-places, that the great burden of their lives is to keep up with the new drugs and the new dodges. He distrusts men who are always going in for new drugs. In surgical results there is too much of the same thing. Take the case of Dieffenbach's operation for squint, a most useful proceeding judiciously applied over a limited area. But he remembers the time when every urchin with a squint was collared in the street and walked into the operating-room to have one rectus divided in order that its opponent should have full power to swivel the eye out in the opposite direction. Everybody was "doing squints."

Removal of the appendages has been similarly overdone; but Tait energetically disclaims all responsibility for this visitation.

His final admonition is as follows:

"If you want a thing done well you must either do it yourself or trust it to a very small number of workers. I do not think it would be too much to ask our Association to place every new drug and every proposal for a new surgical proceeding under the observation of a small, responsible committee, whose judgment should precede anything like a wholesale experiment by the professional public at large. This step would certainly clear away a vast amount of rubbish, would direct more extended research into definite lines, instead of the indefinite and haphazard roads it now runs upon in almost every instance. And I cannot help feeling it would prevent us doing the great deal of harm which is now done in the early stages of even our best proposals."

We cannot undertake to enter into a discussion of Mr. Tait's ideas. Many of his suggestions are quite sensible. But he certainly takes far too narrow a view of surgery, which is not mere mechanics requiring manual dexterity alone. One great trouble with Mr. Tait is that his pathology is so much at fault that he holds it in contempt. We are apt to do so with our weak points. The true surgeon of to-day should be well versed in anatomy, physiology, and pathology. To sink him down to the level of a mere expert craftsman would be degrading. So far from constituting progress, it would mean a lapse into something worse than mediævalism. Modern surgical science will not wait even for a Tait to catch up.

And the surgeon of the future will not be content to be a mere carpenter, who cuts the living for a living.

LIFE INSURANCE FOR PHYSICIANS.

About six months ago we took occasion to speak of the natural improvidence of the practising physician, and of the meagre provision that he generally leaves for the support of his family after his death. The moral which we drew from this fact and which we urged upon our readers was, that medical men, of all others, should insure their lives, so that their children might not be left destitute after the provider had been taken away from them.

We recommended that the physician should first of all become a member of the Physicians' Mutual Aid Association, if there were any in his neighborhood, and then, if he could, take out a policy in some regular life insurance company. The editor of the *Cincinnati Medical News* honored our humble article with a perusal, but it seems to have been a very hasty one, for he evidently misunderstood it completely. We did not advise anyone to insure his life in a mutual life assessment company as opposed to an "old time" company. Indeed, we had no thought of passing judgment upon the merits of the rival systems of

insurance. Reference was made only to the New York Physicians' Mutual Aid Association and to similar societies, if such existed in other States. This is not an insurance company, in the general acceptance of the term, for it has no high-salaried officers and pays no exorbitant agents' fees. Its objects are to furnish pecuniary aid to the widows of deceased members, and also to extend aid to the members themselves in case of need. Members of the Association are entitled to gratuitous treatment in certain hospitals, both general and special, in case of illness. It is an excellent society of medical men, and we are glad to learn that membership in it is rapidly increasing, and that physicians of the State outside of New York City are beginning to appreciate the advantage of belonging to an association of this sort.

We extend to our esteemed contemporary in the shadow of St. Paul's Church, the assurance of our highest regard, and beg him to pause and grasp our meaning before again subjecting us to the shafts of his discriminating criticism.

News of the Week.

The Cholera.—The cable reports the continuance of cholera in the Mediterranean provinces of Spain and even in the interior of the country. It is believed that the disease prevails much more extensively than the reports would indicate, the government having taken measures to suppress telegrams of an alarming nature. The disease appears to be advancing steadily along the African coast of the Mediterranean from Egypt in the direction of Morocco. Telegrams from St. Petersburg assert that cholera is raging at Vladivostock, a Russian naval fortress in the Northern Pacific Ocean. The Russian squadron stationed there has been compelled to leave, and the vessels employed in carrying convicts to the Island of Saghalien have been stopped for the present. Stringent measures have been adopted with regard to all vessels coming from the various ports of Asiatic Russia. The Russian Government has sent several physicians to Asia Minor to make experiments in the treatment of cholera with ferula sumbul, or muskroot, a plant which grows in Turkestan, and which possesses certain anti-spasmodic properties. It formerly enjoyed quite a reputation in Germany and Russia as a remedy for cholera, but has fallen out of use in recent times. Even its name is now unknown to most practitioners in those countries, although the plant is still regarded popularly as an efficient diarrhœa medicine. There have been several cases of sporadic cholera in Ohio which have been widely published in the daily papers, and have caused a great deal of unnecessary alarm to many timid souls. Sporadic cases of cholera occur nearly every summer in the Mississippi and Ohio Valleys, but it is only when the public mind is in an expectant state that these cases cause any apprehension.

Dublin Free from Typhus Fever.—It is stated by the Board of Health in Dublin that there has been no death from typhus fever in the city for the last fourteen weeks, and that probably during the present century so long a period had not previously elapsed without a death from that disease in Dublin.

The Pasteur Institute in Chicago.—Twenty-four persons have been treated in the Chicago Pasteur Institute since it was opened on July 2d. Of these one was bitten by a skunk, two by a cat, and twenty-one by dogs. In twelve cases the Director of the Institute believed the dogs were mad, of the remaining twelve he had some doubts. All the patients were treated by inoculations and escaped without injury.

A Woman's Medical College in Glasgow.—The late Dr. Henry Muirhead left £25,000 in his will to found a college of medicine and dentistry in Glasgow for women.

Dr. Frederick Arnold, Emeritus Professor of Anatomy in the University of Heidelberg, died recently at the age of ninety years.

Dr. James Mathews Duncan, late Lecturer on Midwifery in St. Bartholomew's Hospital, has died in London. Dr. Duncan was born in Aberdeen. After graduating in medicine in his native city, he went to Edinburgh and there became assistant to Sir James Y. Simpson. The latter was at this time studying the action of chloroform, and Dr. Duncan, it is said, was the first person upon whom chloroform anæsthesia was successfully tried. He was called to London in 1877 to become obstetrician to St. Bartholomew's Hospital.

The Marine Hospital Service.—The transfer of this service from the Treasury Department to the Naval Medical Service is said to be contemplated.

Antiseptic Duelling.—A duel was recently fought at a little village on the Belgian frontier in which everything was conducted under strict antiseptic precautions. The sword-blades were first placed in boiling water and then carefully washed in a five per cent. solution of carbolic acid. The surgeons were ready with a corrosive sublimate solution of one to a thousand and a number of gauze pledgets which had been rendered aseptic by thorough baking. Unfortunately for the success of the experiment, the duel was of the ordinary French kind, and the only wound received was a slight cut on the hand, which healed promptly after the application of a small piece of aseptic court-plaster.

Louisville has no Ambulance System, but an effort is being made to induce the city authorities to establish one.

The San Francisco Hospital.—Dr. J. H. Healy, Superintending Physician of the San Francisco City and County Hospital, has filed his annual report for the fiscal year ending June 30, 1890. It shows that 3,984 persons were treated at the institution during the year, of whom 3,679 were admitted since July 1, 1889. Of these, 404 died, and 182 were transferred to other institutions, the rest being cured or discharged improved. The total number of births was 136. The cost of the hospital for the year was $77,305.68.

Orificial Surgery.—The latest fad in medicine is known as orificial surgery. The disciples of this new cult look chiefly to the openings in the human form, believing, with the great bard, that all men have their exits and their entrances, and that if these are preserved in a normal condition the internal regions will take care of themselves. The oriphysicians recently held their third annual meeting in Chicago.

Cyanide of Gold is thought to be the substance used by Koch in his latest experiments to prevent the development of the tubercle bacillus in guinea-pigs, and which he claims he has succeeded in doing.

The Chalubinski Institute.—The sum of $5,000 has been given to establish an hygienic institute in Warsaw, in memory of the late Professor Chalubinski. The donor has modestly requested that his name be withheld, desiring that all the honor be given to Dr. Chalubinski's memory.

Gifts to a Hospital.—The North Adams (Mass.) Hospital recently received most generous offers from three citizens of the town. Mr. William A. Gallup will build a large wing to the building and add private rooms for patients. Mr. A. C. Houghton will assume the old debt of the hospital, in amount about ten thousand dollars, and Mr. C. T. Sampson will lay out about ten acres of land surrounding the hospital as a beautiful park and gardens. Mr. Gallup's gift is as a memorial to his wife, who died about six months ago, and who was President of the hospital and one of the greatest workers in building it up.

The Austin District Medical Society will hold its twelfth quarterly meeting in Austin, Tex., on Thursday, September 25th.

Failure of the Experiment to Vaccinate from Donkeys.—Some time ago Surgeon-Major O'Hara, after conducting a series of experiments, recommended the use of the donkey as a vaccine lymph agent instead of the calf. According to the *Indian Medical Gazette*, the Sanitary Commissioner has now represented to the Government the inadvisability of using the donkey for this purpose, as from recent experiments and inquiries made he found their use would tend greatly to injure the cause of vaccination. In Trichinopoly, where the experiment was tried, the people refused to be vaccinated from the donkey, and treated it with ridicule. By some castes the donkey is looked upon as an unclean animal, and is held as the goddess of ill-luck. Vaccination is still backward and very unpopular with many classes; and it is pointed out that the introduction of the donkey as a lymph agent will render it still more unpopular and prove a bar to its progress.

Overcrowding in Australia.—The *Australasian Medical Gazette* sounds a note of warning to medical men who may think of emigrating thither in the hope of bettering themselves. It asserts that the number of medical men in the Australian Colonies is now very great, and as a consequence professional competition is perhaps more severe than in Europe or the United States. In support of this statement it says that there were lately no less than seventy-eight applications, by properly qualified men, for the post of resident surgeon to the private hospital of a Queensland mining company.

The Medical Practitioners' Protective Alliance is the name of an association formed in Baltimore, with the object of maintaining organized co-operation among practising physicians, for the purpose of protecting themselves against the dispensary abuse and inferior medical schools, and of devising means of improving their financial condition in every honorable way. Dr. J. H. De Wolf is the secretary of the association.

Coca-growing in India.—Erythroxylon coca, from which plant cocaine is obtained, is said by the *Indian Medical Gazette* to have been cultivated with much success in certain districts of the Southern Presidency, especially Tinnevelly and North Arcot. It is noted that the best results were obtained from the plants grown on the uplands, and that those planted in the hot low plains died away. It is intended to gather the leaves and send them to the Government Quinologist for analysis, with a view to ascertain their value as regards the percentage of cocaine.

The Wisconsin Training School for Nurses graduated its first class at the Milwaukee County Hospital on September 4th. The class numbered seven members.

Virginia State Medical Society.—At the meeting of the Virginia State Medical Society, held recently at Rockbridge Alum Springs, the election of officers resulted in the choice of Dr. W. W. Parker, of Richmond, for President, Dr. John W. Dillard, of Lynchburg, Dr. Jacob Michaux, of Richmond, and Dr. H. M. Patterson, of Staunton, First, Second, and Third Vice-Presidents, respectively; Dr. Landon B. Edwards, of Richmond, Recording Secretary; Dr. John F. Winn, of Richmond, Corresponding Secretary; and Dr. R. T. Style, of Hollins, Treasurer.

Female Medical Students in India.—The study of medicine is becoming very popular with the native women of India. At the close of the academic session in 1889 there were 24 female students at the Calcutta Medical College, 14 at the Campbell Medical School, and 5 at the Cuttack Medical School. At Agra, during the year, 7 young women received licenses to practise. At Lahore there were 19, and at Madras 39 female medical students, one of the latter being the first to take the degree of M B. at the Madras University. There were also female students at the Grant Medical College of Bombay, and at the Government Medical Schools at Poonah, Ahmedabad, and Hyderabad. The movement was initiated a few years ago by Lady Dufferin, the wife of the Viceroy of India. Madame Pim, a diplomaed surgeon from Paris, has settled down in Bengalore, and is doing a large practice among the Zenana ladies there. A Bengalore paper believes that there is ample room for a lady surgeon or two in the Mysore Province, and it is said that the Maharajah will offer a scholarship to any girl student of the Maharanee's College, who cares to enter on a course of medical study at the Madras Medical College. It is also stated in the *Indian Medical Gazette* that a large number of female pupils at the Agra Medical School have just passed their final examinations. These include several students who were especially sent by the Durbars of Ulwar and Tezpur and the municipalities of Etah, Fyzabad, and Raipur.

Yellow Fever at Port Limon.—An indignant denial has been cabled from San José de Costa Rica of the report that yellow fever prevailed at Port Limon. It is asserted that there is no yellow fever nor any other contagious disease at the port, nor is there any foundation for apprehension of an epidemic. The Costarricense complain bitterly of the closing of the port of New Orleans against vessels from Limon, and hold that there would be equal justice in closing Limon against vessels from New Orleans.

The Canadian Medical Association.—At the annual meeting of this association, held in Toronto on September 9th, 10th, and 11th, the following officers were elected for the coming year: *President*, Dr. T. G. Roddick, of Montreal; *General Secretary*, Dr. Birkett, of Montreal; *Treasurer*, Dr. W. H. B. Aikins, of Toronto; *Vice Presidents*, Ontario, Dr. A. H. Wright, of Toronto; Quebec, Dr. S. P. Lachapelle, of Montreal; New Brunswick, Dr. S. H. Coburn, of Fredericton; Nova Scotia, Dr. John Stewart, of Pictou; Manitoba, Dr. D. Young, of Selkirk; British Columbia, Dr. E. A. Prager, of Nanaimo; Prince Edward Island, Dr. Taylor, of Charlottetown; Northwest Territories, Dr. E. A. Kennedy, of MacLeod. The next meeting will be held in Montreal.

A Two Hundred Thousand Dollar Libel Suit.—Suit has been entered by the manufacturer of Radam's Microbe Killer, against the *Druggists' Circular*, of New York, for $200,000 damages, the largest amount, it is said, that was ever asked for in a libel suit of this kind. The pleadings show that the action is brought to recover damages claimed to have been done the business of the plaintiff by an article published in September, 1889, which gave the result of an analysis of the Microbe Killer made by Dr. R. G. Eccles, of Brooklyn. The *Druggists' Circular* expresses a desire to hear of any case in which unfavorable results have followed the administration of the Microbe Killer, or of any other fact that would be interesting under the circumstances. It claims to have published this analysis without malice and with the sole intention of protecting the public from the loss of their health and money.

Dr. James R. Goffe has been appointed Visiting Gynecologist to Randall's Island Hospital.

A Successful Strike.—The strike of hospital internes at Ghent has resulted in a victory for the medical officers, and in future the management of the medical services will be under the control of the director and two senior members of the staff.

The First Shall be Last.—There is a curious law in France which decides upon the precedence among twins by asserting that the one born last is the elder. This law is based, it is said, upon the statements of certain medical authorities consulted by the government, who came to the conclusion that the last born of twins was always the first conceived.

Wholesale Asphyxia on Shipboard.—An Italian correspondent of the *Lancet* relates a strange case of gas-poisoning which occurred recently in Sicily. At Milazzo, a seaport of that island, a bark had put in after a voyage from Genoa, having in her hold by way of ballast a number of wine-butts which, encrusted on their insides with tartrates, had, to give them the necessary weight, been filled with salt water. On coming into harbor these butts had to be emptied before refilling them with wine, and for that purpose one of the crew, having raised the trap-door admitting to the hold, went down to tap them and run their contents through the drain-holes into the sea. No sooner had the bungs been knocked out than forth rushed a poisonous gas, which took the man's breath away, and made him fall, a corpse, into the escaping salt water. In ignorance of what had happened, a second mariner, then a third, and finally a fourth went below—each in turn to be asphyxiated instantaneously and fall headlong into the salt water, now of some depth in the hold. As the butts continued to empty the poisonous gas increased, and the captain, wondering that none of the four men reappeared, went, out of curiosity, to the trap-door, only to receive a tremendous rush of the gas in his face, and to fall below, asphyxiated and drowned. The cabin boy, the sole survivor out of a crew of six, seeing what had happened shouted wildly for help to the by-standers on the quay. Assistance soon came, and the stifling fumes, by this time escaped or so diluted as to be innocuous, admitted of the newcomers looking down into the hold. There were the five men, quite dead, floating in the water. The corpses were hoisted up with ropes, and the medical officers, who had now arrived, pronounced them past recovery. They explain the tragic incident, fortunately a very rare one, by supposing that the salt water, enclosed in the wine butts during many hot days of midsummer, had from contact with the incrustation of tartrates developed a fluid which, assuming the gaseous form, becomes a powerful asphyxiant. Had this danger been foreseen it might have been averted by hoisting the butts out of the hold, and then plunging them into the sea, where they could easily have been tapped, and have so discharged their poisonous contents to be diluted and made harmless in the water.

Aristocratic Nurses.—As showing that nursing is becoming fashionable, it is asserted by a writer in the *British Medical Journal* that Princess Helen Cusa is a nurse in the Children's Hospital, Jassy; Countess Asta Blucher has been nursing the invalids of Captain Wissman's force at Zanzibar; Miss Godolphin-Osborne, niece of the Duke of Leeds, is matron of the Leamington Hospital for Incurables; Lady Leveson Gower is a nurse in one of the metropolitan hospitals; and Lady Amberley and Baroness Ebba Bostron were trained at St. Mary's Hospital, Paddington, a few years ago.

Curettage of Soft Chancres.—Dr. O. Patersen, in a paper read before the Syphilo-dermatological Society of St. Petersburg, gives some interesting statistics from the wards of the Alexander Hospital concerning soft chancre. The total number of these cases treated as in-patients, during the seven years 1881–1887, was about 3,000, and the mean number of days they remained in hospital was 27.5. In 1888 the number of in-patients was less than half what it had been in any previous year, and the mean number of days they were kept in was only 20.7. The explanation of this difference is, that during 1888 the treatment systematically pursued was that of scraping out the chancre with a small, sharp spoon, just in the way in which lupus is treated. This plan was found to answer so well that a much larger proportion of the cases could be treated as out-patients than under other methods of treatment, besides which the severer cases which had to be admitted into the wards recovered in considerably less time. An objection to the operation is its painful character; but, according to Dr. Petersen, it is not much more painful than the application of caustics; besides, by a subcutaneous injection of cocaine ten minutes previously the pain can be avoided. Any ordinary antiseptic dressing suffices.—*The Lancet.*

Responsibility of an Operator.—An important trial has lately come to an end in Belgium, in which a medical man, Dr. Deschamps, of Liege, was the defendant. The plaintiff's complaint was that the defendant, in his capacity as surgeon to the Hospital des Anglais, at Liege, had operated upon his child without his consent, the result being that the child was lamed for life. No charges of malpractice or unskilful treatment was made, the whole burden of the complaint resting upon the lack of the father's consent. It appeared, however, that the mother, after having been told that an operation ought to be performed, brought the child again—after consultation, as she said, with the grandmother—in order that it might be done. Long afterward the father, incited, as is supposed, by some malicious or evil-disposed person, appeared for the first time on the scene, demanding enormous damages. The case was tried before the ordinary court, and the plaintiff was successful in obtaining a verdict for 10,000 francs damages. An appeal was arranged, however, and it is this which has now been concluded, the judgment being for the defendant. Dr. Deschamps is to be sincerely congratulated.—*Hospital Gazette.*

A Rival to the Madstone.—A story comes from Connecticut of the cure of a man dying from a snake-bite, the affected leg being already gangrenous when treatment was begun. The recipe was one stolen from a poor old Indian while he was drunk on hard cider, and reads as follows: "Make a ginger poultice from clear ginger and warm water, and place same at pit of the stomach. Take handful of leaves or rods of the common plantain; handful of white ash leaves; equal quantity of horseradish; steep in two quarts of water; take half a gill of mixture once an hour until pain subsides. Take a teaspoonful of mashed bloodroot and bind on the wound, renewing occasionally. When the bloodroot is changed wash the wound in a tea made of black kohosh root." The remedy is said to be just as efficacious in preventing the evil effects of a bite from a mad dog.

Uterine Vomiting Independent of Pregnancy.—Much has been written of late years on the subject of the vomiting of pregnancy and its most aggravated form, hyperemesis gravidarum, or uncontrollable vomiting. Dr. Lamy has recently written on cases in which troublesome vomiting has been observed as associated with other phenomena of the female generative system besides pregnancy. He began with a case of vomiting at puberty. A girl, aged 14, suffered severe pain before her first period. After that period the pain ceased, but an attack of vomiting followed every meal. No drugs were of any avail, and the patient had to be fed with a drachm of beef-tea every half-hour. When the menses became regularly established the vomiting ceased, and did not return during the first pregnancy, six years later. Dr. Lamy related two obstinate cases of vomiting during the period in adult women. In one, vomiting invariably followed sexual intercourse. The patient became pregnant, but after she bore a child the vomiting always returned under the same circumstances as before. Treatment proved unsatisfactory. Lastly, Dr. Lamy noted a case of vomiting at the climacteric. The patient was fifty years old, the period was becoming very irregular, and occasional disturbances of the alimentary canal, especially vomiting, set in. Treatment, as in ordinary dyspepsia, gave relief. This last case might be explained by many physicians as simple gastric catarrh, due to errors in diet or other causes, rather than to changes in the uterine functions. It is clear that the vomiting of pregnancy is very common, and almost normal. On the other hand, vomiting at puberty, during menstruation, after coitus, or about the menopause, must be considered abnormal.—*British Medical Journal.*

The Decline of the Spank Cure.—The Chicago *Inter-Ocean* deplores the waning popularity of this time-honored practice. It says that among the good old customs which are falling into disuse, that of spanking the coming generation into behaving itself is leading the procession. There are no such spankings now as there used to be. Things in the spank line are certainly degenerating, along with the drama, the flavor of strawberries, and phenomenal weather, as the years go by. Children just entering the heated, base-burning epoch of spankhood now have "nerves" and must be humored. They get to balking and sulking, and the family physician is called in when the good old housewife remedy of a warm application of slipper is all that is needed. The spank cure is not appreciated in this generation as it was in the last.

The Shameless Poor versus the Deserving Poor.—In Paris, recently, a family of eight attempted suicide, with such success that only one, the mother of six children, survived. The *Eclair* says, apropos of this peculiarly distressing affair: The man, a draughtsman, has sought work at his profession, but has found none. He is strong; he has good arms and great needs; he offers his strength. He will work at anything, it matters not what; but everywhere he meets the same disheartening response: "No work for you!" Out of work, out of money, and six hungry children. "God," said Briollet, "blesses large families—only, he does not feed them." Death seemed to be preferable to the misery of life. They prepared the charcoal brazier, one helping the other. They stopped up the openings. They embraced one another; they prayed together; they lay down—the mother on the bed with the youngest child, the father near her; the others, side by side, on the floor. And they waited, in sleep or in tears. Toward four o'clock in the morning, the father arose and relighted the brazier. An hour of anguish followed. The mother, who alone survived, has narrated, it seems, that one daughter cried out, that the father threw himself toward his daughter. But from that moment the mother lost consciousness. The Paris Journal continues, that death had had the cruelty to let her live. It is true they did not importune the Department of Charities. But there remains this mortal shame, this horrible crime, a father and mother, brave, esteemed, honorable, industrious, have killed their children and have willed their own death, because worn out by hunger. Much is done for the poor—but nothing is done for the poor who are proud. Official charity assists only the shameless poor, and shameless poverty is often no more than an exploitation of pity. Our system of assistance should be reconstructed from top to bottom. Are the deserving poor helped in New York as they should be, or do the undeserving ones monopolize our uncharitable charities?

Society Reports.

BRITISH MEDICAL ASSOCIATION.

Fifty-eighth Annual Meeting, held at Birmingham, England, July 29, 30, 31, and August 1, 1890.

(From our Special Correspondent.)

(Continued from page 311.)

SECTION IN MEDICINE AND THERAPEUTICS.

THIRD DAY, FRIDAY, AUGUST 1ST.

SIR DYCE DUCKWORTH, PRESIDENT, IN THE CHAIR.

Functional Disorders of the Heart, was the subject opened for discussion by the President. Such diseases, said Sir Dyce Duckworth, are very frequently met with in practice. He referred to those derangements of the functions of the heart which could not be shown during life or after death to be connected with organic lesions. A physician who was a clinical observer was an artist, not a mere scientific man; and he must make use of the varied sciences which threw light on the obscure subject of the cure of disease. Symptoms of disease at the bedside resembled the post-mortem appearances seen in the dead-house, and must be studied alone and treated often without any help from physiology or pathology. He divided functional disturbances of the heart into five groups: 1, Slow pulse; 2, intermittent; 3, irregular; 4, frequent pulse; 5, inordinate vascular pulsation. Slow pulse was most frequently noticed after acute diseases, and was found in cases of malarial poison, after jaundice, or with increased arterial tension. Injuries to the head, meningitis, or cerebral abscess were causes of this form of pulse. In malaria, he concluded that some change had taken place, probably in the nerve-centres. In intermittent pulse there was regularity, but a beat was dropped occasionally. Sometimes this disorder was of but little import, at other times it was highly important. Irregularity was of graver import than intermittency. This disorder of the heart's action might be caused by tea-drinking or tobacco-smoking; and, in such cases, if the patient could be persuaded to have better habits he would get well. The irritation set up by dyspepsia was a frequent cause of intermittent pulse; and it would often be found that the erect posture would put an end to the symptom. He believed that, in such cases, the gastric branches of the sympathetic nerve were in fault. Pulses of high tension, when intermittent, were of graver importance, for the weak heart was apt to fail under pressure. Constant intermission was not always of serious import, and in many cases was due to the excessive use of tobacco, tea, or coffee. Chloroform often removed the intermittency. The causes of irregularity were flatulent dyspepsia, abuse of tea, coffee, and tobacco. The prognosis in such cases depended on the soundness of the heart. It was apt to supervene in gouty patients after middle life. In cases of chronic eczema the irregularity might cease when an attack of itching supervened. The causes of inordinate frequency were to be found in dyspepsia or in profound nervous disorders. Paroxysmal attacks of inordinate frequence were occasionally witnessed in cases of chronic rheumatic arthritis. Bristowe thought that such cases might develop into permanent disease, and terminate fatally. Pulses of this kind might at one time be as high as 200, and then fall to 34 per minute. This form of functional disorder occurred pretty nearly in equal numbers in both sexes; and was most commonly met with in middle life. Rheumatism and syphilis might exist with it. Lastly, in the cases of inordinate vascular pulsation, this was to be found chiefly in middle life, and in leucæmia. No grave morbid change was found in such cases after death. There was some loss of vasomotor control. Hysteria and gout were both causes of this form of functional disturbance of the heart. Then there was the irritable heart of young men, and this was often met with in young recruits for the army and navy although more commonly in the army when drill was too incessant for the strength. Such cases often led to slight hypertrophy of the heart, for which the recruit was dismissed. Graves' disease was probably dependent on neurotic affection, and there were several grades of it. Affections of the cervical ganglia or medulla oblongata might be a cause. Exertion had the power of subduing palpitations, when they were of neurotic causation, but not when due to organic lesions. In some cases of so-called "functional disorders of the heart" the symptom was probably only the precursor of some organic disease. The cerebral system was apparently in fault, and the inhibitory action of the sympathetic seemed to be withdrawn. There was often more or less decay of these centres of nutrition. Sometimes inherited neurotic disease existed. With regard to remedies, he had not found either aconite or digitalis of much service in such functional disorders of the heart. Iron, cod liver oil, and the various bromide salts were sometimes useful.

DR. RICKARDS, of Birmingham, said that the study of functional diseases of the heart had been much cast into the shade by organic disease, and hence they were much less clearly made out. Indeed, it would be hard to find in two text-books the same classification of these diseases. He did not know why Sir D. Duckworth had omitted angina pectoris from the list of such disorders. The irritability of the heart in young men was attributed by Sée, of Paris, to hypertrophy; but this had not been admitted by other authorities, who pointed out that the apex-beat was in its usual position in such cases. He held that it was not possible to be certain that all functional disturbances of the heart were neurotic in character. Angina pectoris was considered by some to be due to increased arterial tension, while others believed that it was caused by ischæmia. Some held that Graves' disease was due to a blood disease. As a rule, functional disturbance was connected with weakness of the organ, so that it was not clear that the nervous system was always in fault. Weak hearts might go on working efficiently until extreme old age, and only break down under undue strain. Slow pulse, or a pulse under forty, must be chronic to be significative. Such cases were not frequent; but frequent enough to be important. They seemed to follow sometimes after injuries to the medulla oblongata, and were never clearly congenital. He mentioned a case of slow pulse in a boy, aged fifteen, who had also an organic lesion of the heart.

DR. SOUTHEY mentioned a case when a man had suffered from slow pulse (pulse 20) for years. He himself had had a gentleman under his care who had, during his life, had a pulse of 30, for thirty years at least, and regular. This man was vigorous in mind and body, and with no symptoms of organic disease of the heart. He was still alive at the age of eighty. Injury to the neck had been mentioned as a cause of slow pulse; but, in one case where the patient had fibroid thickening of the upper membranes of the cord, the pulse was quicker than normal. Charcot, in his "Diseases of the Nervous System," mentioned three cases of slow pulse, and maintained that the medulla oblongata was in fault in these cases. Great mental anxiety might bring on slow pulse; but in most cases of this form of disorder of the pulse organic disease of some kind was traceable. No one cardiac disease was in fault. Dr. Russell, of Birmingham, had collected 38 such cases, and in 30 of them organic disease was found to coexist. In 3 cases of slow pulse, from 26 to 38 per minute, all had been accompanied by organic disease; and all were subject to fits, with giddiness and dyspepsia. All were middle-aged men. The prognosis much depended on the symptoms observed. The brain suffered first and fits were of frequent occurrence. He had found no benefit in functional disturbance of the heart from digitalis or from strophanthus. An albuminous diet had proved of service; that and freedom from exhausting labor were the most serviceable parts of treatment.

Dr. Edison, of Leeds, did not agree with the term functional disease of the heart. All such irregularities, doubtless, were associated with some lesion of the organ, although this might not be discoverable by any kind of examination accessible to the clinical inquirer. It would, he thought, be very unwise of clinical practitioners to cut themselves adrift from experimental physiologists, and not take account of the result of the labors of such inquirers. It must be remembered that a man with a radial beat of 40 per minute might have a cardiac pulse of 80; but the organ might be too feeble to affect the wrist pulse oftener than once in every two pulsations. Thus the fatty heart was often incapable of causing such radial pulsation. Gouty people might have rapid pulsation in consequence, probably, of retention of the secretions, and because the nerve-centres were irritated by these secretions. The rare examples of slow pulse which were met with every now and then were curious, just as a man of six feet seven inches was a curious and rare specimen of the race. After all, the average pulse was merely the average pulse, and persons might have peculiarities in this matter and yet be in a perfectly normal condition. Poisoning by tobacco, tea, and other like substances were other examples probably of poisoning of the nerve centres. In such cases it might happen eventually that the heart would become organically affected. It might eventually become dilated. Men who took long railway journeys and led sleepless and rackety lives were liable to have disorders such as those under discussion, but the difficulty sometimes was to say what cases were to be considered as functional and what cases organic. Angina pectoris had, in his experience, always been associated with some organic lesion of the heart.

Dr. Thomas, of Bournemouth, looked upon functional derangements of the heart as symptoms, and for some years had had a classification of his own for them. The first group of causes of these disorders referred to dyspeptic disease. They were found in catarrh of the stomach, in constipation, and in enlargement of the abdomen from various causes. Next came the neurotic group, and here tea was a very common cause, partly because strong tea tended to produce dyspepsia. The use of tobacco, also, was frequently followed by functional cardiac disturbances; and alcohol, too, was at first a stimulant and then a depressant of the pulse. One of the most common causes of functional heart disorders was onanism or excessive venereal indulgence. Thirdly, chlorosis caused such functional disorders of the heart, and mental disease might also be a cause of such disorders. With regard to angina pectoris, that was an organic disease, and depended on disease of the heart or arteries. Some cases of Graves' disease might exhibit no exophthalmos. The treatment of such disorders consisted in removing the exciting cause.

Dr. Markham Skerritt, of Clifton, observed that there was no reason to say that any particular rate of pulse was abnormal, when there was no physical sign of disease of the heart. In those cases in which people were found to have slow pulses the condition was probably often constitutional. Doubtless, in speaking of functional disturbances of the heart, the pulsation of the organ itself was referred to, and not merely the radial pulse. In cases where the patient complained of short breath on exertion, although it might not be possible to say that organic disease was supervening, yet it might sometimes be predicted, with great probability of the prognosis proving true, when there was disorder of the pulse. It was impossible in some cases to distinctly state that there was no organic disease of the heart; but this might be only temporary and curable.

Sir Walter Foster, M.P., of Birmingham, said that he could only offer some few remarks on the subject of a desultory kind, as his time and thoughts of late had been so much taken up with other topics beside those of clinical medicine. He spoke of the affection styled "runaway heart" and incipient Graves' disease. This part of the subject required further study. On putting patients with that form of functional derangement into the recumbent position but little effect was produced on the rate of the pulse. He had found neither digitalis nor aconite of any service in such runaway pulses, and the only drug that had proved of service in his experience in similar cases of rapid pulse was quinine in large doses, such as ten grains thrice daily. Some years ago a lady consulted him for rapid pulse and slight swelling of the thyroid gland, with proptosis, all of which were symptoms of exophthalmic goitre. She was reduced to the last stage of weakness. He sent her to the bracing air of Rhyl, in North Wales. This lady had not had children for some years, but at Rhyl she became pregnant, and then she became greatly better and nearly quite well. The moral of this was that many of such cases were under the influence of the mind, or under those of sexual emotions. In youth, when the sexual organs were developing, such functional disturbances were commonly met with. He would like to mention, in connection with the treatment of such cases, that they had derived much benefit from the use of the continuous current applied to the sympathetic in the neck. In one lady the pulse was thus reduced five or six beats in the minute, and she did very well after a time.

Dr. Strange, of Worcester, narrated his own case of functional disturbance of the pulse. During the influenza epidemic in February last, he rose one morning feeling very sick. After luncheon he went to the railway, but was too weak to ascend the steps, so he went home and dined. He had no pain, but on going to bed he felt very cold and began to shiver. His pulse was only fifteen or sixteen per minute, and irregular. He had recourse to stimulants (brandy) and a medical friend visited him and suggested that he had angina pectoris. This, however, appeared impossible, as he had no pain. In five or six hours ether and doses of strophanthus did much good. Next night a violent cough supervened, and this continued for three nights. He had gastric catarrh, and then the attack passed off as it had come, leaving him with his normally tranquil pulse and health. Supposing that this attack had only been a little worse, he felt that his pulse might have stopped altogether; and this accounted for the large mortality of certain historical epidemics which had occurred in the Middle Ages and carried off thousands.

Dr. Drysdale, of London, thought that all that was meant by the term "functional disorders" of the heart was that in such cases no symptoms were heard of what was styled organic disease of the heart. His classification of such disorders was according to causes, and he held that, firstly, dyspepsia was a very common cause of such derangements; but that, above all, they were most frequently due to overdoses of nicotine, tea, or coffee. Tobacco heart disorders were extremely common in those days, when even able medical men were in the habit of smoking cigars and cigarettes, and even, *mirabile dictu*, pipes of strong Virginia tobacco. He could not help saying, in passing, that medical men should set an example of avoiding such dangerous poisoning of the nerves; and, doubtless, after this debate, fewer doctors would smoke or use tobacco in any form. Alcohol, too, was a very frequent cause of functional heart disorders; and so were tea and coffee, when strong infusions were partaken of. Onanism was also a most common cause of quick and irregular pulse, and it was often by means of such perturbed palpitations in youths that the dangerous habit might be diagnosed. He thought that conjugal relations were far more rarely causes of disturbances of the heart's action than onanism; indeed, it was rare to see such disease even in young married couples, although these often were rather rash in such matters. Hysteria and insanity were often accompanied by functional disturbance of the heart and so was chlorosis and pernicious anæmia. Angina pectoris, in his experience, was always accompanied by disease of the heart or arteries.

DR. DRUMMOND, of Newcastle-on-Tyne, narrated the case of a gentleman with cardiac hypertrophy, and with a pulse of only 13 to the minute. This gentleman, however, enjoyed fairly good health. He developed influenza and then had a pulse of 36 to 40. He, Dr. Drummond, was suddenly sent for by this gentleman and found him in a fit and with epileptiform convulsions. In a few hours there was another epileptiform seizure, and the pulse fell to 5, 10, or 15 per minute. This slow pulse preceded the attack of epilepsy. In this case, influenza caused slowing of the pulse.

SIR DYCE DUCKWORTH, in reply, said he had left out angina pectoris from his paper because that affection, in his experience, was due to some organic malady. The debate had been most interesting, and showed that in the consideration of functional disorders of the heart attention ought to be paid to the personal factor as well as to the mere symptom. Doubtless the heart in some persons was larger than in others. With regard to treatment, the only suggestion as to special drug medication had come from Sir W. Foster, and the suggestion of large doses of quinine ought to be borne in mind in the treatment of the cases which he had referred to of runaway heart.

DR. HAIG, of London, read a paper "On Some Vascular Effects of Uric Acid." He observed that his object was to explain that the cause of much of the derangements of the heart's action referred to in the previous debate was due to the presence of excess of uric acid in the blood. Some years ago he would have spoken of headache or megrims as the symptom *par excellence* of the retention of uric acid, but he now considered that many diseases, such as rheumatism, epilepsy, gout, and functional heart disease, might be explained by this cause. The tension of the pulse was produced by the irritation caused by this poison, which caused contraction of the arterioles throughout the whole body, and when uric acid was in great quantities in the blood it caused a scanty excretion of urine, and other secretions. When this was the case there was an attack of melancholy, whereas, when the arteries were dilated in the brain and elsewhere, there was a cheerful and hopeful feeling of mind. Alkalies assisted in the excretion of uric acid, while acids tended to diminish the excretion. Suicide, according to Dr. J. Bertillon, was more prevalent in summer than in winter, and he, Dr. Haig, attributed this to the less facile excretion of the poison of uric acid during the heats of summer. Again, many suicides followed the influenza epidemic, and this he also attributed to the retention of uric acid caused by the disease. In fevers the uric acid went from the blood into the liver, spleen, and joints, and this caused pain in these regions and low tension in the arteries. As soon as the fever was recovered from the blood became again overcharged with uric acid. It was in the early morning hours that the excess of uric acid in the blood was greatest, after the acid tide of the night, which was at its height at midnight. On this account rheumatic pain was apt to be worse at night, and rheumatic fever. In the morning there was a high tension pulse, and at that time the urine was often very scanty. By influencing the excretion of uric acid the tension could be lessened. Epileptic attacks supervened when the urine was scanty, and it was then, when the pulse had a high tension, that the fits most frequently occurred. Hysterical attacks also were often due to the same cause. The retention of uric acid would, moreover, best account for the stupor of epilepsy, which was ill accounted for merely from nervous exhaustion, the ordinary cause assigned. The greatest amount of urine was excreted in the daytime, when the alkaline tide was at its height, the least at night, when the acid tide was fullest.

SIR DYCE DUCKWORTH praised the very great pains taken by Dr. Haig in his most careful observations in the retention of uric acid. It was very rare indeed, he added, that English physicians were so patient and persevering in such researches, and this was greatly to his credit.

DR. LITTLE spoke of the power of influenza in the excretion of uric acid. In one case he had found that the excretion of this substance had been quickly promoted by the use of vapor-baths.

DR. DRYSDALE, of London, said that, having read most of Dr. Haig's learned communications, he was greatly pleased with the way in which that author attempted to account for so many painful and distressing maladies by attributing these to the presence of uric acid in excess, either in the blood, the joints, or the internal organs. The misfortune was that the process for the discovery of uric acid was, as yet, so difficult, as compared with that for the quantitative estimate for urea. Consequently very few clinical observers had been able to check the results arrived at by Dr. Haig. He wished to ask a practical question, and that was, What was the remedy which Dr. Haig considered the most suitable for eliminating the excess of uric acid from the system? As he was physician to the same hospital, he believed he was not far wrong in saying that Dr. Haig had great faith in the salicylate of soda; but he would like to hear what he himself said publicly.

DR. HAIG, in reply, said there was an excess of uric acid in the joints in rheumatism and in the blood in epileptic seizures. He could produce an attack of megrims in himself at will by certain drugs. In cases of headache from retention of the acid he first treated the patient by opium and when the pain was relieved he administered salicylate of soda to eliminate the uric acid.

DR. HERRINGHAM, of London, narrated a case of "Intermittent Albuminuria" which he had recently treated in the West London Hospital. This occurred in a boy, who was in-patient at that hospital and in whom the albuminuria faded away in the evening to a very small quantity. After an attack of rheumatism the patient had no albumin for a few days. The results of his study of the case were: Firstly, that the position of the patient was the most influential of all parts of the treatment and that no other factor seemed to produce any particularly striking results. When the patient lay on the back for some time, there was less albumin in the urine; and this he attributed to the position of the kidneys and their blood supply. Diet had but little effect, as was also the case with drugs. Some excretion of oxalic acid was noticed but no casts were seen in the field of the microscope in this case.

DR. DRYSDALE, of London, asked if there was any history of scarlet fever in the case of the boy, and on the author assuring him that there had been no such history, he said that it was a very difficult matter to judge of the importance of such cases as were styled "intermittent albuminuria." His impression was that in almost all such cases, where the albuminuria was clearly made out by heat and nitric acid there was a dangerous prognosis, and that sooner or later the patient was likely to be seized with some of the many complications which caused albuminuria to be rejected by all cautious examiners for life insurance. There were cases where a slight cloud was produced by the use of other agents; but he thought that these were not clearly cases of albuminuria, which required the greatest cantion on the part of the patient to treat it successfully.

SIR DYCE DUCKWORTH said that it was the custom of all examiners for life insurance in cautious companies to refuse cases where albuminuria existed. Doubtless some injustice might be done to certain cases, similar to those mentioned by Dr. Herringham, but as the medical advisers to the companies had but little time to go into the histories of the cases, he considered the rule a wholesome one.

DR. RICKARDS said that Sir D. Duckworth had referred to life offices. His own way of testing for albumin was firstly to boil and then add acetic acid, and then to use the cold nitric acid test, allowing the urine to float on the surface of the acid and watching if a ring formed at the junction of the two fluids. When he detected a cloud in

such cases he could not recommend the case for insurance. In two cases he had recently rejected one died shortly after and the other made no further application to the office. Even apart from any subsequent nephritis, the occurrence of albuminuria was alarming.

DR. EDISON, of Leeds, also considered that the presence of albuminuria was a "danger signal."

DR. HAIG said that the attack of acute rheumatism mentioned in the case was very interesting, in having caused a temporary cessation of the albuminuria, as was also the presence of oxalic acid; both of these circumstances might act on the kidneys and cause irritation and excretion or retention of uric acid. He could not, however, attempt to account for the albuminuria in that case by this supposition.

DR. HERRINGHAM, in reply, said he had not in any way wished to couple Dr. Haig's theory with the history of this case; and he thought that the occurrence of oxalates was too common to be of importance in the history of the case.

DR. SHOEMAKER'S paper was taken as read, in his absence, and the Section adjourned.

TENTH INTERNATIONAL MEDICAL CONGRESS.

Held in Berlin, August 4, 5, 6, 7, 8, *and* 9, 1890.

(Special Report for the Medical Record.)

(Continued from page 307.)

SECTION ON OBSTETRICS AND GYNECOLOGY.

FOURTH DAY, THURSDAY, AUGUST 7TH.

Treatment of Osteomalacia by Castration.—DR. TRUZZI, of Milan, reported two cases treated in this manner. The first case was a woman, twenty-seven years of age, who had suffered since her first pregnancy from osteomalacic pains. When the second pregnancy occurred it was found that the pelvis was already narrowed and it became necessary to induce premature labor. Double salpingo-oöphorectomy was performed. No disease of the adnexa was found. The disease seemed, however, to be arrested, the pains rapidly grew less, and finally ceased entirely, and the pelvic deformity did not increase any further. The second case was one of non-puerperal osteomalacia, occurring in a delicate woman, thirty-four years of age. She suffered from osteomalacic pains, could not walk, had marked right dorsal lateral curvature with deformity of the pelvis, and had diminished in height. Double salpingo-oöphorectomy was performed as in the first case. There was no apparent alteration in the uterine adnexa. The left ovary was, however, somewhat thickened, weighed thirteen grammes, and contained in its centre a sarcomatous nodule. The improvement in the patient's condition following the operation was very noticeable. The author said that an explanation of the benefit derived in these was very difficult to make. Nevertheless, although the remedy is almost a purely empirical one, there is some rational ground for the operation, since it removes all danger of pregnancy with its aggravation of the existing disease, and it also arrests the menstrual function, which in itself is injurious to the patient suffering from this peculiar disease.

Puerperal Osteomalacia.—DR. FEHLING, of Basle, followed with a paper on the nature and treatment of puerperal osteomalacia. He recalled the former grave prognosis of the disease and the wonderful change that was noted in certain cases after the performance of Porro's operation. The improvement following the removal of the uterus and ovaries in these instances led to the thought that ovariotomy might be of benefit even in non-puerperal cases. The speaker had operated in nine instances, and had obtained a cure in eight; one died from obstruction of the bowels in consequence of adhesion of the intestine to the uterus. The patients varied in age from twenty-eight to fifty-one years, and one had suffered from the disease for thirteen years. In studying the cause of the disease examination of the urine and also of the blood gave negative results. The speaker had formerly inclined to the belief that the affection was of an infectious nature, but since observing the good results of operation he had abandoned this view. Jaksch had asserted that the alkalinity of the blood was diminished, but the author had been unable to satisfy himself that this was correct; in the cases upon which he had operated he could detect no difference in this respect before and after the operation. It had been thought that the cure after operation was due to the fact of the cessation of menstruation, but this could not be sustained, for in some of his own cases the women had ceased to menstruate for several years, and yet the improvement did not appear until after the operation. It is a fact, however, that the affection usually seems to advance during the menstrual period. This is deserving of some consideration in our search after the cause of the disease. Other points that demand attention in this regard are:

1. The extremely rapid subsidence of the pain after operation, that felt in the ribs and sternum disappearing before that of the pelvis.

2. The surprising richness in venous and arterial vessels of the extirpated adnexa, with dilatation of the same as in pregnancy, seems to point to a fact of importance in an etiological sense. Macroscopical and microscopical examinations of the extirpated ovaries have, however, failed thus far to reveal any important changes, either in the parenchyma or in the connective-tissue of the organs.

3. It has been shown that a remarkable fertility exists in osteomalacic women, and this fact points to an increased functional activity of the ovaries, for even after the disease is in full progress pregnancy occurs with great frequency.

Reviewing all the facts which have been noted up to the present time, Dr. Fehling was inclined to regard the affection as one residing primarily in a pathologically heightened activity of the ovaries. This leads, through reflex action upon the vaso-dilators, to dilatation of the vessels of the bones, inducing hyperæmia and consequent absorption of the osseous material. The immediate effect of castration is to remove this reflex stimulation of the vaso-dilators, and thereby follows contraction of the vessels and an arrest in the progress of the malady. Considered from this point of view, osteomalacia may be regarded as a reflex trophoneurosis, analogous in some respects to struma and Basedow's disease.

Hæmatocele and Hæmatoma.—DR. J. VEIT, of Berlin, read a paper on this subject. He contended for a more definite and distinct nomenclature of the various forms of hemorrhage within the pelvis. The term, intra-peritoneal hemorrhage, should be held to mean an unconfined hemorrhage into the peritoneal cavity; hæmatocele is encapsulate hemorrhage into the peritoneal cavity; a hæmatoma results from hemorrhage into the connective-tissue. Free hemorrhage into the healthy peritoneal cavity can never give rise to an hæmatocele, the essential condition for which is either complete encapsulation over the bleeding place or slow bleeding into a peritoneal cavity, with more or less numerous adhesions. In hæmatoma the bleeding is stanched by the pressure of the connective tissue lined on the outside with peritoneum.

In the case of intra peritoneal hemorrhage, if the bleeding stops the blood is absorbed; if it does not stop death is the result, for intra-peritoneal pressure on the bleeding-place does not suffice. The diagnosis of free hemorrhage into the peritoneal cavity is based on the general symptoms of anæmia, without any objective symptoms in the peritoneal cavity, if every other internal bleeding is out of the question. Free blood in the peritoneal cavity cannot be felt either in a fluid or in coagulated state. It is generally easy to distinguish between hæmatocele and hæmatoma, and experience teaches that in difficult cases it is unimportant. In both diseases the

presence of a tumor is necessary. As to the treatment of hæmatoma and hæmatocele agreement already exists. In the case of free bleeding into the peritoneal cavity, and with negative result of examination and severe general symptoms, the peritoneal cavity must be opened.

Mr. Lawson Tait, of Birmingham, agreed wholly with the previous speaker as to the desirability of a more accurate definition of the varieties of intra-pelvic hemorrhage. The term hæmatocele might, he thought, be very conveniently employed to refer to hemorrhage within the peritoneal cavity, and hæmatoma might be confined to bleeding within the cavity of the broad ligament. The treatment of each was most diverse. Hemorrhage into the peritoneal cavity demanded immediate abdominal section and ligature of the bleeding-point, while bleeding into the lower ligament might safely be left to itself in the great majority of cases. In hæmatocele all the natural hæmostatics were absent. In hæmatoma the conditions favored immediate coagulation, and the hemorrhage was therefore limited. In hæmatocele there was the chance of a convex swelling above the brim of the pelvis, with a more or less marked convex swelling in the cul-de-sac felt from the vagina. In hæmatoma the swelling was distinct and ovoid (while the fixation of the roof of the pelvis was concave) and was groined down to the bony walls of the pelvis like the roof of the crypt of a church.

Fifth Day, Friday, August 8th.

Electrolysis in the Treatment of Uterine Myomata.—Dr. Georges Apostoli, of Paris, opened the discussion on electrolysis. He referred to the various uses of electricity in gynecology, to the relief of pain and circulatory disturbances (amenorrhœa, dysmenorrhœa, and menorrhagia) effected by its agency, to the arrest in the progress of benign tumors of the uterus which his method of electrolysis afforded, and to the resorption of peri-uterine exudates which could be effected by the use of a galvanic current. He then spoke more particularly of the subject under discussion. His method consisted in the application of galvanic currents, above fifty milliampères, but varying according to the tolerance of the individual patients and the special clinical indications. It was possible that the vaginal application of the galvanic current may give results in certain cases, yet it is inferior to the intra-uterine method. The latter was to be preferred for several reasons: 1, Because by means of it the whole of the current employed is utilized; 2, because we here get the benefit of the antiseptic action of the positive pole, an action which is purely local and is not exerted at the negative pole, or at any point in the interpolar circuit; 3, because the operator is thus enabled to make use of the derivative and cauterant action of the intra-uterine application, treating thus at the same time the endometritis which so often complicates fibromata and peri-uterine phlegmasiæ, ensuring a more rapid, more perfect, and more enduring cure; 4, because in it the pain is less intense, thus permitting of the application of stronger currents, and finally because it ensures a more perfect draining away of the effused blood. The safety of this method was amply proved by the author's personal experience, as he had had only three deaths in over 11,000 operations for various conditions. He contended that the method at least gave relief, while the danger was as nothing compared with the risks of laparotomy, cauterization of the uterine cavity, or the use of the curette. Between July, 1882, and July, 1890, the author had applied electricity 11,499 times to 912 patients, including 531 cases of uterine fibroids, 133 cases of endometritis alone, and 248 of the same affection complicated with pelvic inflammation. Only three deaths had occurred, one being in a case of fibroma, and all were attributable to operative mistakes, and not to any special faults inherent in the method itself.

Dr. Ephraim Cutter, of New York, referred to the history of the application of electricity to uterine myomata, dividing the American literature of the subject into two classes, viz., original, antedating the publication of Apostoli's method, and unoriginal, following that period. He had experimented with electrolysis as long ago as March, 1871, observing the effect of the current upon raw meat. In August of the same year he had tried electrolysis on the human subject, but his patient did not continue treatment. He persevered with the use of electricity, however, making improvements and modifications in the necessary apparatus. In 1887 he reported 50 cases treated by electrolysis, with the following results: 11 cured, 3 relieved, 7 unimproved, 4 deaths, and 25 in which the growth of the tumor was arrested. He believed that there was more danger in the operation than was claimed by Apostoli and other ardent advocates of the method, yet it was of use in selected cases and in experienced hands. As to the manner in which the cure is obtained by this method, he believed there was room for some speculation, for we do not yet know all about the currents of electricity that may flow through the human body. It was the speaker's belief that the electrical current so modified the process of nutrition that absorption was brought about after Nature's methods, and not directly as a result of the application of the electricity.

Dr. Paul Broese, of Berlin, was very sceptical as to the cures supposed to have been obtained by this method. In the first place, no man was infallible in his powers of diagnosis, and it was very possible to make mistakes, especially in the early stages of the growth. But, in addition to this source of error in compiling the statistics, the time that had passed since the alleged cure of many of the reported cases was too short, and it was only after the lapse of a considerable period that we could pronounce definitely upon the reality of the cure.

Mr. W. Dunnet Spanton, of Hanley, reported a number of cases of fibroid tumors of the uterus in which electrolysis had been performed after Apostoli's method. These cases were not uniformly successful, yet, in the greater number of them some good had resulted.

The discussion was continued at some length, no new facts, however, being brought forward, either for or against the procedure. Many of the speakers were inclined to favor the method in suitable cases, although few of them were inclined to agree with Dr. Apostoli as to the almost entire absence of danger. It was the general rule that any therapeutic measure, if it possessed any merit at all, gave the best results at the hands of its originator, and, of course, the more experienced the operator the more would the dangers of the operation be diminished. Others, however, and perhaps the majority of those taking part in the discussion, opposed electrolysis as being ineffective and dangerous, and preferred other measures for the removal of uterine myomata.

Sexual Life of Women after Castration.—Dr. F. Keppler, of Venice, presented a paper embodying the results of a study he had made in the cases of ovariotomy performed by himself. He had performed castration 46 times, obtaining a cure in 39. These operations were performed for the relief of purulent or gonorrhœal salpingitis, oöphoritis, fibroid tumors of the uterus, etc. The following were his conclusions, derived from a study of the physiological consequences of these operations: 1. When the operation was performed on account of salpingitis or other inflammatory process, uterine hemorrhage never occurred subsequently. 2. The conjugata became gradually shortened, and this was the more marked the younger the individual was when operated upon. 3. The uterus became atrophied, the vagina grew shorter and narrower, its mucous membrane became paler, and the labia majora were somewhat thinned. 4. The breasts grew smaller, acquiring a strong resemblance to the male mammæ. 5. The brown pigmentation of the nipple, areola, perineum, and anus disappeared wholly, as did also pathological pigmentation existing in some of the cases; the hair also turned white. 6. The tendency to embonpoint, which is generally believed to

exist after these operations, was not observed by the author. 7. No changes were observed as regards the growth of the hair or the tone of the voice. 8. The sexual desire remained, and was the more pronounced the earlier in life the operation was performed. 9. The operation offers no impediment to marriage; three of the author's cases had married and had lived happily with their husbands for years. 10. A marriage with a castrated woman is the ideal Malthusian marriage, and the only way the Malthusian idea can be carried out without endangering the health and happiness of the woman. 11. In the cases operated upon in early life for inflammatory conditions, no neuroses were seen to develop, which was not the case when women were operated upon late in life for fibroid tumors of the uterus. 12. A favorable influence upon the hemorrhage was observed after operations for myoma, yet in no case did the menopause at once set in. 13. In cases of operation for uterine fibroma, the patients, even those in full maturity, lost all sexual inclination after the operation.

Remote Effects of Removal of the Uterine Adnexa.—Dr. Bouilly, of Paris, read a long communication on this subject, basing his conclusions upon a study of upward of fifty cases observed during a period of the three years from the beginning of 1887 to the end of 1889. Cases operated upon during the present year were too recent to be used in judging of the remote consequences of the operation. The following are the general conclusions which the author drew from his study of these cases:

1. The remote effects of the removal of the uterine adnexa are excellent, and beyond any question when the indication has been furnished by certain actual lesions of the ovaries and tubes. The most important of these lesions are salpingitis and suppurating oöphoritis, and in the second rank may be classed non-suppurating, painful oöphoritis and peri-ovaritis. In these two classes of affections the results of the operation are perfect, and no other therapeutic measure could well replace the radical treatment.

2. The remote effects appear less favorable when the operation has been done on account of certain forms of catarrhal or interstitial salpingitis complicated with parametritis, in which cases total extirpation is difficult of accomplishment.

3. The treatment of nervous disturbances by ovariotomy is permissible only in cases in which the organs are demonstrated to be actually diseased. The ultimate results are the better the more distinct are the lesions found.

4. The removal of actually diseased adnexa never seems to exercise any injurious effect upon the life or after-life of the woman, who in many cases is restored by means of the operation to health and a happy existence.

Gynecological Hygiene for Girls.—Dr. Debacker, of Paris, read a paper on "Preventive Antisepsis of the Genital Organs in Young Girls," in which he urged the most scrupulous attention to cleanliness of the vagina, and held that girls should very early be instructed in the elements of gynecological hygiene. He said also that antiseptic vaginal injections should be kept up for at least three months after child-birth, even though the latter were perfectly normal and were accomplished without any accident whatever.

Extra-peritoneal Hysteropexy.—Dr. Assaky, of Bucharest, read a paper on the treatment of certain forms of deviation of the uterus by hysteropexy (ventro-fixation of the uterus). The following were the indications for and against the operation which the author formulated, basing his conclusions upon the results obtained in a number of cases reported in greater or less detail in the communication:

1. Extra-peritoneal hysteropexy is contra-indicated in prolapse complicated with a lesion of the adnexa. In such cases laparotomy alone affords the operator a means of knowing the extent of the lesions, and it is also the best means of removing the condition. The measure is contra-indicated in cases of adherent retro-deviations, in which cases also laparotomy offers the best results, as it permits us to free the uterus from the adhesions before suturing it to the abdominal wall.

2. Extra-peritoneal hysteropexy is contra-indicated in non-adherent retro-deviations, because one of the elements necessary for the perfect adaptation of the uterus to the abdominal wall is the relaxation of the uterine ligaments, a condition existing only in cases of prolapse.

3. In simple non-complicated prolapse, extra peritoneal hysteropexy is a simple and rapid operation and one which is wholly devoid of the dangers attributed to it by many whose fears are grounded on lack of experience.

Massage in Retro-deviations of the Uterus.—Dr. Doederlein, of Leipsic, presented a short communication on this subject, in which he related some improvements that he had adopted and which he thought would simplify the method very much and thus serve to render it more popular.

Intra-uterine Tamponade.—Dr. Auvard, of Paris, read a paper on this subject. The procedure advocated by Dührssen in 1887 consists in drawing down the cervix, after delivery has been accomplished, as near the vulva as possible, and then with the aid of forceps or simply with the fingers alone, filling the entire uterine cavity with twenty per cent. iodoform gauze. The tampon is left in place for twenty-four hours, and is then withdrawn by pulling on the end of the gauze left hanging out of the vagina. The latest communication on this subject was made by Dührssen before the Gynecological Congress in Freiburg in 1889. This author had collected the reports of sixty-five cases, among which were six deaths, three from syncope, and one each from septicæmia, eclampsia, and tuberculosis. The last two cases could not be attributed to the method itself, and it is doubtful whether the operation could be justly blamed for the other four deaths. But even admitting these cases there would be but four deaths out of sixty-five, or rather out of sixty-seven (for the speaker had two successful cases of his own to add), thus giving a mortality of only about six per cent. The method is thus shown to be a safe aud effectual one. In the three cases in which death from syncope following hemorrhage occurred, the operation was performed too late, after so much blood had already been lost that the patients were not able to recuperate when the bleeding had been stopped.

The following were Dr. Auvard's conclusions: 1. Intra-uterine tamponage is a hæmostatic measure devoid of any real danger, since, in the cases thus published, the mortality at most was only six per cent., and in all probability even less than that. 2. It is by far the best hæmostatic method which we can employ in post-partum hemorrhage. 3. It deserves at least to be faithfully tried, and will probably be eventually adopted in obstetrical practice.

Dr. Pasquali, of Rome, had employed this method in post-partum hemorrhage, which is of rather frequent occurrence in malarious regions, using the same procedure described by the preceding speaker. He regarded it as far superior to intra-uterine injections of hot water.

Dr Fochier, of Lyons, had used intra-uterine tamponade in two cases of placenta prævia. He had found that it sometimes caused rather strong expulsive pains.

Dr. Dührssen, of Berlin, said that he had collected many more cases since publishing his last statistics. He did not now recall their exact number, but it was in the neighborhood of two hundred. The results obtained in these cases were equally good with those previously published, and confirmed the opinions held as to the utility of the method in controlling post-partum hemorrhage.

Dr. Vulliet, of Geneva, said that he had long before applied tampons to the non-puerperal uterus. In some countries the uterus is, however, very sensitive to the action of iodoform, and in Switzerland especially he had often seen symptoms of pronounced iodism after a tam-

ponade of this kind. He believed that tampons of iodoform gauze should be used with great caution in mountainous countries, where goitre is common, and where the inhabitants are very susceptible to the action of iodine.

Dr. Kochs, of Bonn, said that it was not necessary to use iodoform gauze, for simple sterilized gauze was all sufficient. This was indeed the method now used by Dr. Dührssen. The speaker showed an apparatus which he had devised for sterilizing the gauze for this purpose. He recalled the fact that some authorities had recommended the artificial inversion of the uterus in cases of post-partum hemorrhage.

Dilatation of the Uterus.—Dr. Vulliet, of Geneva, exhibited some photographs and casts showing to what an extent the uterus could be dilated by the method which he had described in a previous communication. Some cases, indeed, resist such extreme enlargement as he had obtained in the specimens shown, but even in these the greatest possible amount of dilatation can be obtained by the use of the tampon. One great advantage of this method of dilatation is that it is painless, and another, and by no means unimportant one, is that it allows of the maintenance of perfect drainage of the uterine cavity. He had obtained excellent results from the employment of this method in cases of chronic endometritis which had resisted all other therapeutic measures.

Aseptic vs. Antiseptic Laparotomy.—Dr. G. Rein, of Kieff, read a paper on this subject, in which he endeavored to establish the indications and contra-indications for each method. He thought that the aseptic method would grow in favor, yet would never, from the necessity of the case, be able entirely to supersede the antiseptic. The latter would always be necessary in microbic diseases of the peritoneum, in cases in which there were purulent collections in or near the peritoneum, in operations where the surroundings were unfavorable, as often was the case in private practice, when it was necessary for any cause to leave the operation uncompleted, and when there was occasion to fear septicæmia.

Dr. Landau, of Berlin, presented a long communication entitled "Diagnosis and Treatment of Hydro- and Pyo-salpinx."

Sixth Day, Saturday, August 9th.

A Contribution to the Histology of the Normal Endometrium.—Dr. H. J. Boldt, of New York, presented a paper with this title, embodying the results of some studies which he had recently made. He had found that the utricular glands of the mucosa were not only surrounded by a net-work of muscular structure at the base of the glands, but that the muscularis accompanied the glands throughout to the surface of the endometrium. This condition had hitherto not been described by any one, although Barnes speaks of Ercolani mentioning the intermuscular stratum of the uterine mucosa, yet in Ercolani's work it is not mentioned, consequently the speaker believed that Ercolani only recognized and described the muscular fibrillæ traversing the adenoid substance. At the base of the glands the muscular structure is four to six spindles in thickness, whereas it gradually becomes thinner toward the surface, so that at the mouth of the glands only one spindle can be demonstrated. Specimens hardened in chromic acid and mounted in glycerine show this condition better than those mounted in Canada balsam, which makes the protoplasmic substance indistinct. For purposes of demonstration places where the epithelium is detached are also better. The speaker demonstrated the histology with microscopic specimens and drawings. Physiologically their importance is that this muscular structure serves to cause the epithelial products, namely, the mucus, to be exuded into the cavity of the uterus.

Myomotomy.—Dr. Charles Boisleux, of Paris, followed with a paper on this subject. While at the clinic of Dr. Martin, of Berlin, he had had the opportunity of examining ten cases of myoma, in which Dr. Martin had performed supra-vaginal amputation of the uterus, followed by removal of the cervix, either through the vagina or by the abdominal wound. In these ten cases he had made cultures from pieces of the mucous membrane, taken from the fundus and also from that part of the cervix which, in the ordinary methods of operating, would have been left within the peritoneal cavity. In four of these ten cases he found micro-organisms in the cultures made from the mucous membrane taken from the fundus, in one case the germs being so numerous that it was impossible to count them on the gelatine plate. In two cases inoculation experiments with guinea-pigs and mice showed these microbes to be pathogenic. In seven of the ten cases he found micro-organisms in the pieces of mucous membrane removed from that portion of the cervix which in the ordinary supra-vaginal operation would have been left as a pedicle to infect the peritoneal cavity. As a result of these observations the author advised strongly that the most rigorous antiseptic measures be taken in the operation and that the pedicle be thoroughly cauterized in all cases.

Asepsis and Antisepsis.—The author then said a few words on the relative advantages of aseptic and antiseptic operations in the abdominal cavity. By aseptic operations is understood those which are carried out with no other irrigation than that with boiled water, while in antiseptic operations solutions of carbolic acid, corrosive sublimate, etc., are used. The aseptic method may be employed in operations upon simple ovarian cysts, subperitoneal myomata, and extra-uterine pregnancy. Antiseptic measures are called for in all cases of malignant tumor, pyosalpinx, suppurating ovarian cysts, and whenever there is any purulent collection whatever. The amount of pus has nothing whatever to do with the question of infection. The sole point to be considered is that of the nature (the virulence) of the material. The peritoneal cavity may be flooded with benign pus, and no harm would result, whereas a single drop of virulent pus might easily cause the death of the patient. As we are unable as a rule to tell concerning the nature of the pus in the abscess or tumor to be operated upon, the only safe rule in such cases would be to employ the most strict antisepsis.

The Operative Treatment of Myoma of the Uterus.—Dr. Fritsch, of Breslau, read a paper on this subject. There was, he said, no more difficult operation than the removal of a fibroid tumor from certain situations, it was a capital operation and one attended with risk to the life of the patient. Since a fibroid was not a malignant growth it might be asked whether it were justifiable to endanger the life of the woman for the sake of the removal of such a tumor. He thought it was justifiable—even more so in fact than the removal of a carcinoma. In the latter the most that could be promised was the prolongation of life for a time but in the case of a myoma the result was certain cure if the patient survived the immediate effects of the operation. He then reviewed the different operations which had been employed for the cure of myoma, and first castration. It is true that the myoma would generally shrink after the artificial menopause as well as after the natural one, but it was still there, and might eventually suppurate and lead to septicæmia and the death of the patient. The operation was allowable, however, in two cases, first when the patient was very weak, and secondly when the tumor was small. The second operation, and the one to be preferred in most cases, was enucleation of the tumor. This may possibly be done so as to permit of a subsequent pregnancy, although the author had never seen pregnancy occur in a case which had been so operated upon. The operation which he preferred above all others was, however, the removal of the entire uterus and its adnexa. He then spoke of operations for myomata of the broad ligament, of their difficulties and dangers, and of the means best adapted to avoid the latter or at least to reduce them to a minimum.

Correspondence.

ARE THEY THE BEST LAWS?

To the Editor of the Medical Record.

Sir: It seems rather surprising that you, who with voice and pen have so earnestly advocated the cause of higher medical education wherever and whenever opportunity has presented, should, in an editorial article published in the issue of June 14th, have brought discredit on the Legislature of the State of New York because of its enactments of last year relating to medicine, which, if closely studied, will be found to be among the best laws relating to the practice of medicine which have ever been placed on the statute books of this State. The statement contained in the article of the date above referred to, to the effect that a student may pass the preliminary entrance examination at any period within three years after having commenced the study of medicine, is clearly an error. In 1889 a law was passed making it obligatory, for a person desiring to enter upon the study of medicine in any one of the medical colleges of the State, previous to registration (unless a graduate of some academic college empowered to grant the degree of Bachelor of Arts), to pass the regular and usual Regents' examination. Those who were opposed to the enforcement of this law were instrumental in having a bill introduced in both branches of the Legislature, during the session of 1890, entirely abolishing any previous enactments relating to the requirements of a preliminary education as embodied in the law of 1889. Those of us who had been instrumental in passing the law of 1889 were earnest, not only in framing a law which would tend to advance the standard of medical education in the State, but were likewise desirous of so framing the law that no hardship would come to those about to embark in the study of medicine. It was represented to the advocates of the abolition of entrance examinations that the law of 1889 drove foreign students from our State medical colleges to the schools of Philadelphia and Baltimore, because they were not sufficiently familiar with our language to pass even so simple an examination. Acting on these representations, which were undoubtedly made in good faith by the representatives of the colleges (of New York City more particularly), the law of 1889 was so amended as to allow a student one year's time after entering upon the study of medicine, to meet the requirements of a Regents' examination, such examination being conducted under the direct supervision of an accredited officer of the State Board of Regents, and such examination papers becoming part of the public records of the State of New York. Is not such legislation a step in the direction of higher medical education, as compared with the state of affairs previous to 1889, when the State exacted no test whatever from those about to enter upon the study of medicine, even as to their competency in the three R's? The framer of the law of 1889 is the same gentleman who submitted to the alteration embodied in the present law, and from the congratulatory letters and resolutions which he has received, there is no doubt that the profession generally recognizes the eminent services which have been rendered to the cause of higher medical education by Dr. R. P. Bush, Member of Assembly from Chemung County. The Legislature of 1890 has likewise passed a law which, when its provisions go into effect (1891), will make it impossible for any person, no matter where graduated as M.D., to practise medicine within the borders of the State without having submitted to the same or equivalent tests exacted from those studying and graduating in the State. As to your strictures on the three board Medical Examiners' bill, it need but be stated that every honorable effort was made by the Committee on Legislation of the State Medical Society, through its Chairman, Dr. D. B. St. John Roosa, Dr. Daniel Lewis, and others prominent in the profession, to prejudice the Legislature in favor of a single board, to be appointed by the Regents of the University without any instructions as to the creed or sect in medicine of the appointees; but the other plan (a Board of Examiners for each recognized school of medicine in the State) appeared to be more popular, and we had naught to do but bend to the will of the majority. One other thing, however, we did accomplish, and that was to make the bill proposed by our opponents practically ours as far as the final examinations are concerned, and under the law as amended the same questions will be asked of all students coming up for the right to practise medicine in the State, no matter before which Board they appear, in all the subjects but Materia Medica and Therapeutics; the licentiate standard is to be the same in each Board, the examinations are to be conducted under the direct supervision of the Board of Regents, the results are to be verified by an officer of that same body of educators, and the examination papers are to become part of the records of the State of New York. We did not accomplish what we contemplated, but we *have* established the general principle that the State has the last right to pass upon the qualifications of one who desires to practise medicine within her borders. This is a step in advance, and if the spirit as well as the letter of the law is carried into effect there will be applause instead of regrets for this added legislation, even though we did not carry our point. Other legislation was enacted by the law-makers of 1890 (Care of the Insane, an Act to Prevent Blindness, etc.), but my lines have already strung themselves into unexpected length; yet an apology for this writing will be apparent to those who have read the article in a July number of the London *Lancet*, which, taking the Record article of June 14th as authority, editorially attacks the manner and matter of medical legislation in the United States with a vehemence which is undeserved, because it is unjust. The medical legislation enacted by the Legislature of the State of New York during the session of 1890, if properly carried into effect, while not all that might be desired, is the most radical advance step which has been made in the direction of higher medical education since the codification of the medical laws.

Respectfully,

Maurice J. Lewi, M.D.

71 Lancaster Street, Albany, N.Y.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 7 to September 13, 1890.

By direction of the Acting Secretary of War, a board of medical officers, to consist of Colonel Edward P. Vollum, Surgeon; Major George M. Sternberg, Surgeon; Major Albert Hartsuff, Surgeon; Captain William E. Hopkins, Assistant Surgeon, is constituted to meet in New York City on October 15, 1890, or as soon thereafter as practicable, for the examination of candidates for admission into the Medical Corps of the Army. S. O. 213, par. 8, A. G. O., Washington, D. C., September 11, 1890.

Corson, Joseph K., Major and Surgeon. By direction of the Acting Secretary of War, relieved from duty at Fort Sherman, Idaho, and will report in person to the commanding officer, Washington Barracks, District of Columbia, for duty at that station. S. O. 212, par. 4, A. G. O., September 10, 1890.

Heizmann, Charles L., Major and Surgeon. By direction of the Acting Secretary of War, relieved from duty at San Antonio, Tex., and will report in person to the commanding officer at Fort Clark, Tex., for duty at that station, to relieve Captain Edward B. Moseley, Assistant Surgeon. S. O. 211, par. 23, A. G. O., Washington, D. C., September 9, 1890.

MOSELEY, EDWARD B., Captain and Assistant Surgeon. Upon being relieved by Major Heizmann, will report in person to the commanding officer at San Antonio, Tex., for duty at that station. S. O. 211, par. 23. A. G. O., Washington, D. C., September 9, 1890.

CARTER, EDWARD C., Captain and Assistant Surgeon. Granted leave of absence for one month. S. O. 108. par. 2, Headquarters Department of the Columbia, September 6, 1890.

JARVIS, NATHAN S., First Lieutenant and Assistant Surgeon. By direction of the Acting Secretary of War, relieved from duty at Fort Verde, Ariz. Ter., and will report in person to the commanding officer at San Carlos, Ariz. Ter., for duty at that station. S. O. 208, par. 2. A. G. O., Washington, D. C., September 5, 1890.

WOOD, LEONARD, First Lieutenant and Assistant Surgeon. Granted leave of absence for one month, to take effect on or about October 20, 1890, with permission to apply for an extension of one month. S. O. 74, par. 1. Department of California, San Francisco, Cal., August. 30, 1890.

WOOCHULL, A. A., Major and Surgeon. On surgeon's certificate of disability, is granted leave of absence for one month, with permission to go beyond the limits of the department. S. O. 122, par. 1, Department of the Missouri, September 5, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending September 13, 1890.

WOOLVERTON, THEORON, Medical Director. Ordered to the Philadelphia, September 15th.

PENROSE, THOMAS N., Medical Inspector. Detached from the Richmond.

GARDNER, J. E., Passed Assistant Surgeon. Detached from the Albatross.

DRAKE, N. H., Passed Assistant Surgeon. Detached from the McArthur and ordered to the Albatross.

BERRYHILL, T. A., Passed Assistant Surgeon. Detached from the hospital, Mare Island, Cal., and ordered to the McArthur.

HEFFINGER, A. C., Passed Assistant Surgeon. Ordered before Retiring Board, October 1, 1890.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 13, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	34	17
Scarlet fever	37	3
Cerebro-spinal meningitis	1	1
Measles	46	7
Diphtheria	37	13
Small-pox	0	0
Varicella	2	0
Pertussis	0	0

Doctors not Wanted in Southern California.—Dr. William H. Dukeman, of Los Angeles, Cal., writes: "The city of Los Angeles, Cal., with about sixty thousand resident population, comes to the front with relatively more than three times as many physicians as any city in the United States. And still they come! Los Angeles has a climate, too, where people generally do not need the services of a doctor. The climate is known to be conducive to good health. There is indeed very little sickness of any kind here. Children thrive scarcely without a pain. No summer diarrhœa, no dysentery, no cholera infantum, no fevers, no malaria appear on the list of sickness. The doctor is almost unknown to them. His office is his castle and the climate kindly demands no one to get sick and enter not into his office, for verily, bad tasting medicine and sunshine are antagonistic. Los Angeles is a prosperous city. The doctor in the East reads of this and without investigating as to the number of doctors here or as to his chances of getting any practice he too hastily packs his grip for the land of prosperity and a paradise on earth. When he arrives here he is at once captivated. As he walks along our business streets the glistening letters *Doctor, Doctor, Doctor*, shining in gold and silver on almost every second-story window of the business blocks makes him nervous. He at once concludes that his colleagues are getting wealthy and at first impression at once hastily looks around to secure himself a place. His name soon shines with the others. But alas! who ever hears of the doctor. He may issue advertising sheets to make himself known. He may tell of his lucrative practice he left back East. He may tell of the remarkable cures he effected and of the remarkable surgical operation he performed. But alas, there is nothing here for him to do. He awaits anxiously day after day in his office for a patient. They are like the letter that never came. It is only a matter of a short time when he gets disheartened and sick and is the patient of his sympathizing friend doctor in the same row. After a few consultations with each other as to the prognosis, two are complaining of the same trouble and soon not only one doctor is missing but two have disappeared. Where have they gone? They are never heard of again, yet they continue to come to meet with the same fate, and disappear in the same mysterious manner. Doctor, beware! Southern California is a remarkably healthful climate but indeed it is very unhealthful for doctors. They soon die."

Hints in the Business of Practice.—The successful practitioner needs no hints. But he who is ambitious to "get there," is often in need of counsel. In the *Cincinnati Lancet Clinic*, August 2, 1890, we find the following, which may mean "good business," but is somewhat remote from strictly "good morals:" A patient should always be kept waiting a few moments; it calms agitation and leads them to think you have another client in your private office. Always open and close the inside door of your private office, so as to leave the impression that you have just dismissed a patient from your inner sanctum. It is best also to rattle a few silver pieces of large size. This reminds the outside client that fees in cash are in order. In consultation the great secret of success is to know how to listen; a patient always desires to unbosom himself to a medical confessor. Show me a good listener, and I will show you a man with a large practice. Be sympathetic and patient, giving the client's tongue full swing. Some will talk much, some but little. Do not interrupt a patient's conversation, as it will lead to prolixity; if he does not talk much make him repeat the most interesting details of his case. This produces a grand moral effect, and as good thinkers are often poor talkers, you will often be mistaken for a savant and highly esteemed by the patient. Be careful that no detail of the consultation shall turn to your disadvantage. One of the most vigorous precepts of charity in medicine make it imperious to console and reassure a patient, leading him to always hope for a cure, even though you know the malady to be incurable. Never make a slight affection appear to be slighter than it is. The doctor in slight illness should give positive assurance that he can cure the malady—in time. As a general rule a patient loves to persuade himself that he has been in great danger, and this compensates for the medical fees he pays. It is bad policy not to make a patient realize that he owes you something more than money can repay. Permit him to feel under personal obligations. If he

thinks you saved him from death when he was really in no danger, do not tell him to the contrary. Avoid dangerous exclamations such as fall from the mouths of honest young practitioners in their first innocent verdancy, as for instance: "Ah! it's nothing. You are only a little indisposed. A little dieting will remedy all. Don't take medicine when you do not need it." Physicians who are honest, or rather impolitic enough to tell the truth are not money makers, nor are they esteemed by their clients. Most people who visit a doctor desire to be told that they are ill. To tell them the contrary is to make them out asses. Nine people out of ten who visit a doctor's office are but slightly indisposed, but tell them the truth and they will seek some other physician for consolation. The men with the largest practice are the patient listeners and greatest liars. These two things are prerequisites for success. A doctor may be a talkative man and converse with his clients, but the brainless, silent, and austere physician will beat the most brilliant conversationalist in the pecuniary emoluments of the profession. Make it a point never to allow a patient to leave your office without a written prescription. It is also good policy to give your client written directions as to diet, etc. Don't be afraid to waste prescription paper on any patient. Fill in boldly the *recto* and the *verso*, and the client feels that he is getting his money's worth. The young doctor who says to the patient, "Never mind a prescription; go to the pharmacist and get a dose of salts," is an ass who will learn better after a while.

Sauce for the Goose is not Sauce for the Gander.—There was once a rich woman who discovered that she was about to become a mother. She did not wish to become a mother, for to do so would put her to some inconvenience and for a short time interfere with her pleasures. So she sent for her physician, who was very noted and respectable. As a result of preventing her from becoming a mother she died. The doctor certified that she died from peritonitis. Her remains were prepared for burial by a fashionable funeral director. Her funeral sermon was preached by a fashionable clergyman. The fashionable doctor attended the funeral. Everybody mourned the death of the estimable Christian woman. Everybody was satisfied. "Because," said they, "whatever a rich woman, a noted doctor, a fashionable undertaker, and a swell clergyman do is all right." There was once a poor cigarette girl, named Annie Goodwin, who discovered that she was about to become a mother. She did not wish to become a mother, for to do so would prevent her from ever making a living, except by a life of shame. So she sent for a doctor named McGonigal. As a result of preventing her from becoming a mother she died. The doctor certified that she died of peritonitis. Her remains were prepared for burial by an undertaker named Merritt. She had no funeral sermon, but was buried secretly. The police heard of it and arrested the doctor, the undertaker, the woman in whose house the cigarette girl died, a little boy, a girl friend of the dead woman, and the girl's lover. And everybody said it was horrible that so many persons should have conspired to murder the cigarette girl. They even wanted to lynch the doctor. "Because," said they, "unless such things are done by a rich woman, a noted doctor, a fashionable funeral director, and a swell clergymen they are frightful crimes."—*Twentieth Century*.

A Plethora of Medical Journals.—The *American Lancet* says, editorially, that seven new medical journals have lately been started in the interests of as many medical colleges. Other colleges, in self-protection, must follow, so that we are entering upon an epidemic of new medical journals of large proportions. It would seem as if we would soon have a medical journal for every medical college, and every hospital and dispensary. If to these we add the publications of the several medical societies, a bewildering mass of medical literature will lie before us in quantity appalling to the most diligent student of medical science. The reasons for this new departure are not far to seek. One large institution, ambitious to advance more solidly in the direction of making its influence felt in the profession, started a medical journal From its own ranks it was able to fill this with valuable contributions. Its effects were noticed by other institutions, and, seeming desirable, they also started similar journals. Thus the stream started and grows as it rolls onward. That these journals are for other purposes than medical journalism is apparent from the fact that they are sent to the profession either free or for nominal sums. This can be done, as the object is not to make the journals pay in and by themselves, but rather to promote the interests of individual institutions and those connected with them. What the outcome of this move shall be no one can certainly tell. Clearly, however, it will continue so long as the separate institutions find that it pays. But it would seem as if the pay would diminish in proportion as the practice became more and more general. It would seem also that in many instances it would be difficult to secure the needful material of suitable quality for any great length of time. In all cases it will, after a time, become a tiresome labor. Thus, for reasons of a personal nature, most colleges will drop these publications, and utilize those already established for the publication of their work. They will ascertain that even their personal ambitions are attained more easily without a college organ. They will find that the labor of teaching satisfactorily, added to the cares of a large practice, consumes so much energy that little is left for the cares of medical journalism. Thus the cycle will be complete, and medical journalism will return more completely to those devoting most, if not all, their attention to it.

The Mortality of Widowers from Phthisis.—MM. Destrée and Gallmaerts have come to the conclusion in comparing the mortality from phthisis of bachelors, married men, and widowers, that the last are very much more subject to this disease than either of the other classes. The same statement holds good for all ages, and it is, they say, also true that widows are more liable than single women to die of phthisis. The authors do not think this is to be explained, except by direct contagion of wife to husband or husband to wife. They cannot think irregularities and excesses indulged in by widowers can be answerable for it, for advanced age does not seem to make any difference. They would ascribe it to infection occurring during married life, the disease claiming its second victim some time after the death of the first.—*The Lancet*, August 2, 1890.

How the Patent-Medicine Business is Worked.—"These firms of manufacturers of proprietary medicines, nine out of ten, live solely by the newspapers, and sometimes are admirably managed. I know some establishments in which there is a regular staff employed; I know something about them, because they try to bribe me to certify to the value of their concoctions. As I say, there is a regular staff. There is the literary man, who writes the letters, giving marvellous accounts of marvellous cures; there is the artist who shows the patient before and after taking twenty-two bottles of the medicine; there is the poet, who composes poems upon the subject; there is the liar, who swears to what he knows isn't true, and the forger, who produces testimonials from his own imagination. Without exaggeration, I should say that nine out of ten of these proprietary medicines are frauds, pure and simple; the real business is advertising for dupes. The medical part of it is but a side issue. I am pretty sure, if I were to pound up brickbats, and spend $100,000 in offering it at a dollar an ounce, as a sure cure for some disease which cannot be cured, I should get back at least $110,000, thus giving me $10,000 for my trouble. Nine-tenths of the medicines sent out in this fashion have no more curative properties than brickbat dust."—CHARLES F. CHANDLER, M.D.

WHAT IS ORTHOPEDIC SURGERY?[1]

BY NEWTON M. SHAFFER, M.D.,

ATTENDING SURGEON IN CHARGE OF THE NEW YORK ORTHOPEDIC DISPENSARY AND HOSPITAL, CONSULTING ORTHOPEDIC SURGEON TO ST. LUKE'S HOSPITAL, NEW YORK.

THE recent action of the Orthopedic Section of the New York Academy of Medicine in appointing a committee to secure for orthopedic surgery an official recognition by the Tenth International Medical Congress has been successful. Orthopedic surgery is placed, by this act, upon the same plane with the other special branches of medicine and surgery, and an important duty is imposed upon those who will assemble in Berlin to participate in the proceedings of this newly created Section. It would seem, from the many replies which have been received by the committee in response to the circular letter which was sent to those interested in orthopedic surgery, that there exists a very general desire to aid this important department of surgery. Over one hundred replies have been received from English, Continental, and American surgeons. With a few exceptions the replies have been favorable to the views and wishes of the committee.

Of those who have expressed doubts as to the advisability of creating a special Section of Orthopedic Surgery at the Congress, some have plainly said that this special Section was not necessary; others have stated that in certain localities the treatment of deformities was influenced by a class of men who were not regularly educated surgeons; while others, again, see difficulty in drawing the line between general and orthopedic surgery.

These facts raise some important questions, which, it seems to the writer, should be discussed by the members of the Orthopedic Section at its first meeting in Berlin; and the remarks that I have the honor to present have been suggested by the evident differences of opinion that exist regarding the status of orthopedic surgery. And the writer desires to state that the opinions here expressed are his personal views only, and that the committee appointed by the Orthopedic Section of the New York Academy of Medicine (of which the writer has the honor to be a member) is in no way responsible for them.

It seems unnecessary on this occasion to consider orthopedic surgery from a, strictly speaking, historical stand-point. A few historical facts may be mentioned, however, which bear upon the rise and progress of the treatment of deformities.

From the time of Andry the word "orthopedic" has been identified with the treatment of deformities, and an "orthopedist" has been one who treated deformity. But it was not until Stromeyer, in 1830, demonstrated the feasibility and the value of subcutaneous tenotomy and myotomy that "orthopedics" obtained its first firm foothold in the profession. Both before and after Stromeyer's time, however, mechanico-therapy was the fundamental part of the treatment of deformities. The introduction of subcutaneous tenotomy and of subcutaneous myotomy supplemented the treatment of deformity by mechanical means. Subcutaneous surgery did not dispense with the mechanical element of treatment, it rather emphasized its value and necessity. And it is fitting that we should note that the first great advance in orthopedic surgery occurred in Germany, under the influence of Stromeyer's teachings, and that his methods soon became recognized and practised in all parts of the world.

The status of orthopedic surgery in 1844—about fourteen years after Stromeyer's methods were introduced—is very clearly shown by the essay[1] of Dr. Henry J. Bigelow upon orthopedic surgery. In this work Dr. Bigelow quotes largely from Stromeyer, Guérin, Bonnet, Velpeau, Phillips, Duval, Dieffenbach, and Little. The subjects treated by Bigelow, in addition to club-foot, lateral curvature of the spine, torticollis, etc., include both stammering and strabismus. The operation for the last-named condition has long since been recognized as belonging to the special department of ophthalmology, while the former was long ago abandoned. It seems clear, however, from Bigelow's essay, that, at the date he wrote, orthopedic surgery, so far as operative treatment is concerned, was synonymous with subcutaneous tenotomy and subcutaneous myotomy, and that any condition requiring either of these operations was to be classed under orthopedic surgery. A few years later, or about 1852, an American surgeon, Dr. Henry G. Davis, published his essay, in which he advised the use of elastic traction by means of a portative apparatus in the treatment of hip-joint disease. He also demonstrated the value of traction apparatus for overcoming the deformities occasioned by chronic articular lesions. The treatment of Pott's disease by means of the antero-posterior spinal apparatus was also demonstrated by Dr. Davis and Dr. C. F. Taylor, and the subject of the mechanical treatment of chronic joint and spinal disease received a marked degree of attention from the surgeons of the United States especially.

In this field Dr. Lewis A. Sayre and Dr. Charles Fayette Taylor became very conspicuous. They amplified Dr. Davis's apparatus, and devised many forms of apparatus for the treatment of chronic and progressive deformities, and under their leadership the treatment of chronic joint and spinal disease became a distinctive feature of the American school of orthopedic surgery, and another era in orthopedics, second only to that of Stromeyer, was inaugurated.

Up to about 1870, or thereabouts, it would therefore appear that two important factors had aided in placing orthopedic surgery upon a satisfactory basis. First, the introduction of subcutaneous surgery by a German surgeon, and, second, the introduction of the portative traction method of treatment of chronic joint disease by an American surgeon. Of the former it may be said that subcutaneous surgery is rarely used in the treatment of chronic deformity without after-mechanical treatment, which after-mechanical treatment is oftentimes more important and essential than the cutting operation, and special skill and training are often required to apply it successfully. Of the latter we may safely say that it is not until the mechanical treatment has proved inefficient that cutting measures are, as a rule, thought of, and that when cutting measures are deemed necessary the after-treatment calls for little else than simply surgical dressings which do not demand a special orthopedic training to apply. The introduction of the traction splint in the treatment of chronic joint disease, as well as the introduction of the antero-posterior splint for Pott's disease,

[1] Read before the Orthopedic Section of the Tenth International Congress, Berlin, August 4, 1890.

[1] Manual of Orthopedic Surgery: the Boylston Prize Essay for 1844. Published in 1845 in Boston.

enlarged the field of practical orthopedics very much. "Preventive" surgery, the highest aim of surgery, became an important factor in the treatment of this class of chronic deformities. By the judicious use of traction apparatus, portative or otherwise, deformity can be prevented, and in many cases the disease producing deformity can be arrested. And even after the deformity of chronic articular disease has become pronounced, it can, in many cases, be overcome or greatly modified without any cutting operation. Indeed, the tendency of orthopedic surgery has always been toward conservatism. Its principal victories have been won in this field, and it would seem to be a great error to lose sight, in any way, of the principal factor which has contributed so largely to its present position.

Up to this point, or about 1870, it will be seen that orthopedic surgery had not invaded the field of general surgery. Availing itself of all that contributed to the relief of deformity from its conservative stand-point, it found many difficult problems which it did its best to master. It took hold of, and cared for, a much neglected class of humanity—a class that had long been neglected by the profession at large. Even at this day the general surgeon, as a rule, cares but little for orthopedic work. He is fully occupied in a large field which is every day becoming more exacting, while the orthopedic surgeon is devoting himself to a department which has none of the brilliancy of operative surgery, which requires much patient attention to mechanical detail, which demands special facilities for altering and modifying apparatus, and a special training and education which very few surgeons have received.

It is not many years ago, however, that general surgery began to invade the domain of orthopedic surgery. This is especially true since the Lister method has become so universally accepted. The knife, the saw, the chisel, and the osteoclast have become potent factors in the reduction of obstinate osseous deformities. Knock-knee, bow legs, old and obstinate cases of club-foot, and other conditions are relieved by the direct surgical method, without special after-treatment, except simple surgical dressings. This marks another era in the treatment of deformities, and is a legitimate advance in *general surgery*. And it was about this time, also, that joint resections began to attract the marked attention of surgeons of the United States.

To some orthopedic surgeons these innovations of general surgery have proved a stumbling-block. They diverted the attention from the hard and rugged paths of orthopedic work, *per se*, to the brilliant work of the general surgeon. I know myself that the allurements of the operating-table are very great, for about this time I had my own attack of "surgical fever," which, I am happy to say, proved a self limiting fever of comparatively short duration. But it raised the questions then, as it raises them now, Where shall the line be drawn? What is orthopedic surgery? Shall orthopedic surgeons be general surgeons as well, and shall general surgeons be orthopedists? If these questions are answered in the affirmative, there is no room for a special Orthopedic Section in the Berlin Congress.

Reference has already been made to Bigelow's work, published in 1845. If we compare it with Sayre's work on "Orthopedic Surgery and Diseases of the Joints," published in 1876, or with Bradford and Lovett's work on "Orthopedic Surgery," published in 1890, we will see that the tendency of modern orthopedic surgery is to invade the field of general surgery. Bigelow's work teaches subcutaneous tenotomy and myotomy, plus special mechanical treatment, and nothing more. It does not mention diseases of the joints or Pott's disease of the spine. It deals with the subject of the mechanical treatment of chronic deformity in a meagre way, a subject which is full of brilliant promise in the future. It suggests a field which has never been fully developed, and which rests with orthopedic surgery to develop, viz., complete and scientific methods of mechanical treatment, which when fully developed, will represent as much of real value to the human race as general surgery itself. It already represents a great deal—especially in the mechanical treatment of chronic joint and spinal disease—for since orthopedic surgeons have done so much to render plain the early diagnosis of joint and spinal diseases, mechanico-therapy can prevent the occurrence of deformity, and can frequently arrest the disease in its first or non-deforming stage. And still more, when the articular disease has advanced, and pain is present, or when deformity is progressive and abscess is about to form, or has already formed, mechanico-therapy, properly understood and applied, can hold out to the sufferer more than the operative or general surgeon. In the field of chronic articular disease alone there is enough to do, and enough for the orthopedic surgeon to learn, without invading at all the field of general or operative work.

Let us see the position Sayre takes in 1876. His work, already mentioned, covers, generally speaking, the conditions treated by Bigelow in 1844, and adds to the list "Diseases of the Joints." This is to be expected, for the author's greatest reputation is based upon his experience in the treatment of joint and spinal diseases. He is especially strong in his description of joint and spinal conditions, ample attention being given to diagnosis and prognosis. He devotes much space to excision of the joints. The great strength of his work, however, lies in its orthopedic part, or in the description of deformities and their mechanical treatment. The work is one of the pioneers in an important field, Dr. Louis Bauer having covered somewhat the same ground a few years before. The part of the work that is of the least value *per se* is the part which treats of joint excisions, for the reason that the subject is well considered and amply discussed in contemporary surgical literature; while the part which dwells upon orthopedic surgery is novel, interesting, and in its way classical.

Bradford and Lovett, in 1890, group all deformities under one head of "Orthopedic Surgery," and reject the qualifying title of "Diseases of the Joints," adopted by Sayre. In addition to the conditions treated by Bigelow and Sayre, we find these authors include several new titles. Among them are the "Cerebral Paralysis of Children," "Pseudo-hypertrophic Paralysis," "Dupuytren's Contraction," "Webbed Fingers," and "Functional Affection of the Joints." They extend the surgical aspect of the treatment of deformities and give a large portion of their work to resection of the joints, amputation at the hip-joint, laminectomy, osteotomy, osteoclasis, etc. It seems unnecessary to call attention to the excellent and thorough way in which the (strictly speaking) orthopedic part of the work is executed. It is rather the object of the writer to call attention to the unnecessary invasion of the field of general surgery, in a special treatise on orthopedic surgery, when the purely surgical aspect of the conditions named is amply covered in the current surgical literature of the day.

None of the writers I have referred to define orthopedic surgery in their works, and the definitions given in the various dictionaries are familiar to us all. I have found none that seems sufficiently definite, or that covers the ground from the stand-point of modern orthopedic surgery. Under these circumstances I found myself, several years ago, called upon to define orthopedic surgery, by the class at the University Medical College, at a time when I was connected with the college, and I then ventured upon the following definition:[1] "Orthopedic surgery is that department of general surgery which includes the mechanical and operative treatment of chronic and progressive deformities for the proper treatment of which specially devised apparatus is necessary." I would modify this definition to-day so that it would read as follows: "Orthopedic surgery is that department of surgery which includes the prevention, the mechanical treatment, and

[1] The Present Status of Orthopedic Surgery, New York Medical Journal, January 26, 1884.

the operative treatment of chronic or progressive deformities for the proper treatment of which special forms of apparatus or special mechanical dressings are necessary."

No one doubts, myself least of all, that the orthopedic surgeon should be, from the stand-point of education, a surgeon in every sense of the word; that he should be a well-educated medical man, with ample clinical experience, before he enters the field of Specialism. In short, it seems to the writer that the orthopedic surgeon should take a step in advance of the general surgeon, and that his education should include all that is necessary to make a general surgeon before his study of mechanico-therapy is commenced. As one thus equipped enters the field of orthopedic surgery he will, if he is wise enough to resist the temptation to become an operative surgeon, find many valuable mines to be explored, and much to be learned that is as yet untouched by any writer. And he will find ample work without invading the field of the general surgeon, just as he will find in all parts of the civilized world very many surgeons who are amply qualified to perform all the operations of surgery, and but very few who can intelligently devise and apply apparatus in the various and varying conditions of chronic deformity.

The needs of orthopedic surgery are clearly shown when we appreciate how thoroughly general surgery is taught in all the universities and colleges, while, on the other hand, mechanico-therapy—a very wide and important field—is too apt to be totally ignored. The result is that the work that should fall into the hands of the educated surgeon is relegated to the commercial instrument-maker. We have only to look at the barber-pole of to-day to recall the position of surgery in former years, and it is not impossible that in a few years the opprobrium that attaches to mechanico-therapy will become a thing of the past, and that we may have a class of surgeons interested in orthopedic work who will be orthopedic surgeons in the strictest sense of the word.

From the stand-point here taken, and as a matter of experience, it seems to the writer that the invasion of the field of general surgery by the modern orthopedist is unnecessary and uncalled for. It further seems to the writer that it can only bring discredit upon a new and important field of work—what is even further removed from general surgery than ophthalmology or laryngology. This invasion will direct the attention of the profession to the weak point in the armament of those who combine general surgery with orthopedic work; and it will, if persisted in, in the future break down the lines between it and general surgery. The remark of a prominent general surgeon to the writer, after reading the latest work on orthopedic surgery, is not, perhaps, so much out of place. He said, "The next work on orthopedic surgery will likely tell us all about fractures and dislocations." The fact that the plan here proposed will necessarily limit the operative work of the orthopedist does not lessen either the importance or the honor of the work that lies before him. Operative surgery has its own place, and in orthopedic work that place should be second; and operative surgery should be used by orthopedists only as it supplements mechanico therapy. Orthopedic surgery is as yet in its infancy, and needs men with strong heads and strong hearts, men who are willing to work and study and wait, and to those who do this there will be, I am sure, an ample reward.

And looking at the subject from the stand-point of our meeting here in Berlin, we may learn another lesson. The only possible excuse for the foundation of a special Section of Orthopedic Surgery at this Congress is the rapid rise and development of mechanico-therapy, especially in the United States. There would be no true orthopedic surgery to-day if mechanico-therapeutics had not been studied long and patiently by a comparatively small body of intelligent surgeons. And if the committee who addressed their petition to the Congress, asking recognition, had relied upon the record of orthopedic surgery in the field of joint resections, amputation at the hip-joint, laminectomy, osteotomy, etc., I fancy that the committee would have been referred, and rightfully so, to the Section of General Surgery.

In closing my remarks I feel that I ought to state that the conclusions reached in this paper are based upon an experience of nearly thirty years in orthopedic work.

In 1873 I found myself in charge of the Orthopedic Service of St. Luke's Hospital, with no restrictions as to the operative work of my own department. I soon found that the purely surgical aspect of the work was very attractive, and that my interest in the patients under my care was gauged by their present or prospective operative value, and that the conservative or orthopedic side of the work was becoming less interesting. After mature reflection it became apparent that the operative field was well represented in the eminent surgical staff of the hospital, and that it was clearly my duty to develop and establish the principles of orthopedic surgery. After reaching this conclusion I voluntarily turned over to my colleagues all the purely operative work which required no orthopedic treatment after operation, and from that time up to the day of my resignation I operated only on those cases which would necessarily remain under my care after operation. Soon after my appointment as surgeon in charge of the New York Orthopedic Dispensary and Hospital, an attempt was made to combine a general surgical staff with the orthopedic work. At first it seemed to be just what was needed, and while questions of jurisdiction were sometimes raised there was no conflict between the surgical and orthopedic departments. The real difficulty appeared later, when it was found that the junior medical officers seemed to lose their interest in the orthopedic work, while they were very active in the purely surgical work. The hospital was gradually becoming a surgical hospital rather than an orthopedic one. It became apparent to the trustees after a while that the institution was drifting away from its avowed object. Subsequently the surgical staff retired, and since that time the institution has been, strictly speaking, an orthopedic one.

As the medical officer in charge of the New York Orthopedic Dispensary and Hospital, and having control of its surgical policy, I have for several years—and since the retirement of the active surgical staff—operated only on those patients who required special orthopedic care after operation. All other cases requiring surgical operation have been referred to some general hospital; and I have pursued the same course in my private practice—that is, I have referred all patients requiring surgical operation, who have not demanded special orthopedic care after operation, to a general surgeon. And this, I believe, is the proper position for the orthopedic surgeon to take. During my service at St. Luke's Hospital it was made apparent, very soon after my appointment, that the resident house staff took little or no interest in the orthopedic ward. Their interests, as young and recently graduated medical men, were in general surgery and general medicine. Aside from this, though they were all picked men, very few of them seemed to possess the mechanical ability which is an essential element of success in orthopedic work. After a few years' effort to keep the house staff interested—an effort which failed—I was obliged to ask the hospital authorities for a special assistant.

At the New York Orthopedic Dispensary and Hospital it has sometimes been difficult to secure the attention of the junior staff during a period long enough to fit them for future orthopedic work. At the end of six months or a year they may regard themselves as fully equipped orthopedic surgeons. On the other hand, we have had able men as assistants, whose college and competitive examination records were high, but whose mechanical instincts were lacking. These men were clearly out of place in orthopedic work. My experience proves that it requires an exceptional man to succeed in orthopedic practice. If he possesses mechanical tastes and ability, and devotes

himself to orthopedic work for a sufficient period, he will almost surely succeed in reaching a high place. But if he attempts at the same time to do the work that would naturally fall to the general surgeon, he will, sooner or later, become the latter in effect, if not in name. And if he does not possess in a high degree an educated appreciation of the various and complex mechanical problems which will constantly confront him in daily practice, he will very likely turn to operative measures when there may be no need for such a step.

Nor can anyone expect to equip himself as an orthopedic surgeon in a short time. After graduation, and a term of service as an *interne* in a hospital, a course of study covering at least five years (including a wide clinical experience in dispensary and hospital work) should be demanded of those who expect to become orthopedic surgeons; orthopedic surgery lies wholly within the domain of "chronic" surgery. The junior medical officers in large general hospitals see but little of this class of surgery. On the other hand, they acquire during their hospital residence a wide experience in "acute" surgery. No one can acquire a safe clinical experience without a prolonged study of many cases, and in the chronic joint department of orthopedic surgery one may wait several years before seeing the end of one's first case.

A great deal will be expected of the orthopedic surgery of the future, and it seems to the writer that the sooner the followers of orthopedic surgery realize that it has enough in itself to sustain its well-earned reputation without encroaching upon other grounds, the better it will be for orthopedy. I feel a natural embarrassment in thus presenting my views, but I also feel that it is a duty which the present occasion demands; and if my remarks are regarded as embodying the conclusions of one who desires to see orthopedic surgery occupy the high place it deserves, I shall be wholly satisfied, and if they aid at all in solving the question which heads this paper, I shall be content.

THREE CASES OF CÆSAREAN SECTION, ONE OF WHICH NECESSITATED PORRO'S OPERATION.

By H. F. BIGGAR, M.D.,

CLEVELAND, O.

Case I.—Mrs. S——, aged twenty-eight, German, in height four feet, weighed fifty-five pounds. Perfect physically except a rachitic pelvis. Married five years, with four impregnations. In each of the three former births the physician destroyed the child to save the mother. Earnestly desiring a living child, at the expiration of eight months of gestation she came to the Huron Street Hospital. At full period labor began at 8 A.M., December 16, 1886. At 9 P.M. of same day, when os had dilated to the size of a silver dollar, and before the escape of water, the child was removed by laparotomy, after the method of Sänger. Time of operation fifteen minutes. Immediately on removing the child and placenta a hypodermic injection of thirty minims of ergot, normal fluid, was given. Mother and child saved. Was assisted by Drs. J. C. and J. Kent Sanders, Myra K. Merrick, A. K. Smith, J. C. Norris, and Lena E. Hitchcock.

Case II.—Mrs. K——, aged forty-three, home Akron, O., German parentage, mother of two living children and one still-born at seven months. After seventy-two hours of labor, on August 6, 1888, her physician telegraphed, "Come prepared for a Cæsarean section." Found pulse weak and rapid, and patient very exhausted. After anæsthetizing, corroborated the diagnosis of the attending physician, viz., that of a fibroma of neck and body of uterus which rendered it impossible to reach the os. Delivered the child and placenta by Cæsarean section, after which the uterus with tumor was removed after the manner of Porro. The weight of child was twelve pounds, and of tumor ten pounds. The child had been dead several hours previous to operation. The patient improved up to the tenth day, when an oozing of bright blood from the stump, which was external and held by Keith's clamp, was noticed by the patient. The doctor was summoned, but before he could reach the patient the hemorrhage had been so great that the patient did not rally. If in the hospital the hemorrhage probably could have been controlled and the patient saved. Was assisted by Drs. O. D. Childs, W. Murdock, L. S. Ebright, and J. W. Rockwell.

Case III.—Mrs. W——, aged thirty-four, home Madison, O.; mother of two living children. Previous births were normal. Labor began June 1, 1889, under the care of a midwife. After five days of unsuccessful labor physicians were called, who found transverse presentation with a rupture of the womb in the lower anterior part. Upon my arrival the patient was in a state of collapse, with marked septicæmic symptoms. Though the recovery from low down rupture is the one most likely to occur without an operation, yet an immediate delivery seemed to demand a Cæsarean operation, as every effort to deliver the child had been unsuccessful, which was quickly done. The incision of the womb extended to and through the rupture. A partially decomposed child at full term was removed. The patient rallied well for twenty-four hours, but died from septic poisoning seventy-four hours after operation. It is not known whether the midwife gave ergot, and if so the dose. Was assisted by Drs. A. L. Gardner, of Painesville, O.; J. V. Winans, of Madison, O., and A. B. Allyn, of Thompson, O., In these three cases thorough antiseptic surgery was followed. Case III. was at a farmer's house, and operation at 2 A.M. In this case the child was large, weighing twelve pounds; male. The abnormal position of fœtus may have caused the rupture of womb. It would be more satisfactory did we know whether ergot had been given. A skilled physician at the onset of labor would probably have delivered the child without great difficulty. Lerschmann says a ruptured uterus occurs in but 1 to 1,331 cases, and is one of the most appalling accidents in midwifery.

Dr. Charles A. L. Reed says: "All cases of complete rupture should be submitted to abdominal section as soon as the condition of the patient, with reference to shock, will admit, and for the following purposes: 1, To explore the abdomen; 2, to remove all foreign bodies; 3, to cleanse the peritoneum; 4, to close the rent if the labor should have been short and the uterus not seriously damaged; 5, to remove the uterus if the labor shall have been long and that organ seriously damaged."

A CASE OF INSUFFICIENCY OF THE INTERNAL RECTI RELIEVED BY TENOTOMY OF BOTH EXTERNAL RECTI.

By S. G. DABNEY, M.D.,

PROFESSOR OF PHYSIOLOGY AND CLINICAL LECTURER ON DISEASES OF EYE, EAR, AND THROAT, HOSPITAL COLLEGE OF MEDICINE; VISITING SURGEON TO EYE AND EAR DEPARTMENT, LOUISVILLE CITY HOSPITAL, LOUISVILLE, KY.

As ocular insufficiencies occupy just now a considerable degree of attention in the profession the following case is perhaps worthy of record.

A. B——, aged thirteen, consulted me on October 17, 1889. His mother gave this history: Many of the family, herself included, were subject to severe and intractable headache. The little boy had been under the care of oculists almost constantly for four years. Each oculist—and he had been treated by three—had ordered a different glass. None of the glasses had given much relief.

The chief symptom in the case was a sensation of burning in the eyes and pain both in and over them on any attempt at reading, writing, or other occupation requiring vision at a short distance. The patient complained, too, that he frequently saw double under such circumstances. He could distinguish two kinds of headache, one induced by disorder of the stomach and the other by the strain on his eyes.

There was manifest hypermetropia of .5 D. The total, revealed by the use of the sulphate of atropia, was 1 D.

The glasses which had been prescribed were convex spherical, varying between these limits. Vision was $\frac{20}{20}$.

On converging to a point 15 to 12 inches distant, one eye, usually the right, could be seen to turn outward and the patient would complain of diplopia. More minute examination of the muscular condition was made with Steven's phorometer and gave the following results: At a distance of 18 feet—insufficiency of internal recti, 6°; power of adduction, 2°; power of abduction, 12° (the same or nearly the same in both eyes). At a distance of 15 inches — insufficiency of interni, 15°. There was no hyperphoria.

On October 30th tenotomy of the external rectus of the right eye was performed, and the insufficiency at a distance of 18 feet exactly corrected. There was still left an insufficiency at 15 inches of 4°. This operation improved the patient's condition very decidedly. He has never been annoyed with double sight since. As the cut muscle reunited and gained in strength, however, there was still some burning and pain on use of the eyes. Prisms were used to exercise the weak muscles. On November 25th examination showed at 18 feet insufficiency of interni, 3°; abduction, 12°; adduction, 20°. At 15 inches, insufficiency of interni, 8°.

On November 27th tenotomy of the left external rectus was made, over-correcting the insufficiency and producing internal strabismus with homonymous diplopia for distant objects. A limiting conjunctival suture was so adjusted that the diplopia disappeared when the object was carried about 20° toward the patient's right. This strabismus and consequent diplopia gradually diminished and had quite disappeared by December 11th, when the muscle was again firmly united. Examination December 23d showed perfect equilibrium, both at distance of 18 feet and at reading distance. The patient was directed to begin using his eyes ten minutes at a time and increase five minutes every day. Following this plan he was soon able to study an hour and a half without inconvenience, and was far less subject to headache than previously. The headaches he suffers from now are always preceded and caused by disordered stomach. Renewed examination on May 19th showed this state of affairs unchanged.

Two or three points in this case seem worthy of note:

1. That the patient had been under the care of three oculists of extensive experience, and each of the three had simply prescribed a weak spherical glass and attributed the failure to get relief to malaria, impoverished state of the system, and so on.

2. The very slight power of adduction, as shown by the ability to overcome a prism with base outward, in looking at an object 18 feet distant. The marked increase in adduction power between the date of the first operation and that of the second I believe to be due largely to the "ocular gymnastics" from the use of prisms.

3. The fact that the operation which gave relief not only fully corrected the insufficiency but produced a temporary internal strabismus of about two weeks' duration. That such over-correction is necessary is the doctrine laid down by the text-books, but it seems to be frequently overlooked by operators.

4. What was not accomplished by the operation is also of interest. Though the headache from ocular strain, the diplopia, and the inability to use the eyes were all relieved, the patient still suffers from occasional digestive disturbance and consequent headache.

In view of the wonderful and far-reaching influences of anomalies of ocular muscles, and the brilliant cure of distant affections wrought by correcting such anomalies, as claimed by a few enthusiasts, the result in this case is worthy of note.

The Decadence of the Little Toe.—According to Pfitzner, the little toe of man is degenerating. In thirty-six per cent. of the cases he has observed it had only two instead of three phalanges.

THE PROPRIETY OF OPERATIVE INTERFERENCE IN GUNSHOT WOUNDS OF THE ABDOMEN.

By DWIGHT DICKINSON, M.D.,

SURGEON, U. S. N.

THE following notes may assist in determining the propriety of operative interference in cases of gunshot wounds penetrating the abdomen.

On the evening of January 26, 1890, J. R. S——, U. S. N., white, a strong, healthy young man, twenty-one years of age, received a gunshot wound in the abdomen while under the influence of alcoholic drinks and engaged in a fracas ashore at Vallejo, Cal.

The patient was helped by his comrades into a small boat and taken across Napa Creek to his vessel, the U. S. Receiving Ship Independence.

When first seen by a medical officer, at 6.15 P.M., one hour after the receipt of injury, a circular opening was found in the abdomen, large enough to admit the tip of the little finger, one-half inch below, and two and one-half inches to the left of the umbilicus. The respirations were 30 per minute, pulse changing from 120 to 140. There was no marked bleeding from the wound. The urine was drawn by catheter, and found of normal character. Patient vomited, several times, glairy mucus. On account of shock it was at first deemed advisable to postpone operative interference. Hot bottles were applied to feet, and a subcutaneous injection of sulphate of morphine, one-fourth grain, administered.

The symptoms of stupor and weak, frequent pulse not disappearing, the restlessness and respiration increasing, an explorative laparotomy was decided upon, and, assisted by several naval surgeons, I performed the same three hours after patient was wounded.

The incision reached from just below the umbilicus, in the median line, to about one and a half inch above the symphysis pubis. After opening the peritoneum a moderate amount of blood escaped. The intestines were carefully drawn out and examined for perforations. They were kept covered by towels wrung out of hot water while exposed. As far as the examination went, there were twelve perforations of intestines and omentum. Those of the former were closed by Lembert's sutures. One of the perforations had injured a large mesenteric artery, which was bleeding freely on exposure. This was ligated and the bleeding stopped.

During the operation the patient's condition grew alarming. The respirations reached 60, and the pulse about 180 and feeble. At this stage it was decided to discontinue the search for further perforations. The intestines were sponged off and returned. Three deep and three superficial sutures, a drainage-tube of hard rubber, iodoform, antiseptic gauze and cotton, held in place by bandages, finished the dressing of the wound. Patient was put on a dry mattress and made comfortable.

In the following night patient gradually rallied from the operation and the stupor vanished. He was given occasional doses of Magendie's solution of sulph. morph., and ice pellets relieved the retching. No stimulants were needed. After the operation the patient vomited blood once.

January 27th.—Morning temperature, 98.6° F.; pulse, 140; respiration, 30. Is perfectly conscious and rational. Urine drawn off by catheter. Complains some of continuous pain in abdomen, at times very severe. Dressings not disturbed. Hypodermic injections of sulph. morph. one-sixth grain. Iced milk in small quantities. Temperature remained normal during the day, respirations about 30 per minute. Pulse showed a tendency to become more frequent and weaker. In afternoon commenced stimulants. Brandy, half ounce, every hour. Extremities warm all day.

Evening: Drainage-tube removed and soft rubber one substituted. Discharge serous.

January 28th.—Patient died at 4.25 this morning, of

heart failure, thirty-two hours after operation. Autopsy, at 1.30 P.M.: Found a moderate amount of bloody serum in abdominal cavity. No blood. Recent adhesions of small intestines. The intestines above injury distended with gas. Two openings in small intestines were discovered which had not been closed at the time of operation. The bullet—calibre 32—was found buried in muscular structure just above right great sciatic notch, the track being downward, backward, and to the right. Bladder uninjured.

Although the patient lived but thirty-two hours after the operation I think the latter can be called a partial success, from the fact that he rallied and regained consciousness. I am convinced that the hemorrhage from the mesenteric artery was sufficient to have destroyed life very soon had the vessel not been tied.

The advantages claimed are, that by regaining consciousness the patient could have made a will had he so desired, he could have given testimony relative to the shooting, and he could make religious preparation for death. The last-mentioned act was done.

NAVY YARD, MARE ISLAND, CAL., July 22, 1890.

WORK IN THE EAR DEPARTMENT OF THE VANDERBILT CLINIC.

BY HUNTINGTON RICHARDS, M.D.,

NEW YORK.

THE following brief statement of the work done in the Ear Department of the Vanderbilt Clinic, between January 1, 1888 (the date of opening), and May 24, 1890 (on which day the fifteen-hundredth new case was recorded), will interest those readers of the MEDICAL RECORD who have paid special attention to aural diseases, and also those who may be curious to learn something definite regarding the growth and method of work pursued at the clinic.

Until the establishment of the "Vanderbilt" there never had existed in the out-patient or clinical department of the College of Physicians and Surgeons a special clinic devoted exclusively to diseases of the ear. The aural department is the youngest of the ten for which provision has been made within the walls of the building on the corner of Sixtieth Street and Tenth Avenue. It is also, I believe, the smallest of all our clinical departments, being but a baby in size as well as years when compared with such departments as those of General Medicine, General Surgery, and Children's Diseases; and the data herewith about to be presented therefore fall very far short of serving as a measure of the sum-total of work done by the Vanderbilt Clinic; while as an evidence of steady growth and of careful and thorough work they may be taken as a fair example of the methods and history of the entire institution up to date.

The system of recording every case applying for treatment, enjoined upon us by the managers of the clinic at its opening, has in the aural department been followed out with great care. I am certainly keeping within bounds in saying that the average length of our clinical histories would be represented by twelve lines of foolscap paper, while many of them have greatly exceeded this length. In reading over the whole fifteen hundred histories, as I did before compiling these statistics, I found but six instances wherein no diagnosis had been entered, and wherein the clinical notes were too brief or too imperfect to allow of my supplying the omission. Four other cases were recorded as improper subjects for treatment in our department, and one other was set down as too restless for diagnosis. Among the 1489 remaining patients the following diagnoses were clearly established:

Otitis media catarrhalis chronica in 595 cases, among which were included 132 cases of impacted cerumen. Otitis media purulenta chronica was found 431 times. Of acute catarrhal otitis media there were 142 instances; of acute purulent ditto, 97. In 56 cases a diagnosis was made of subacute catarrhal otitis media. In 9 instances the diagnosis was recorded as acute middle ear catarrh, with an existing perforation of the drum-membrane, and in 4 instances as chronic catarrh with ditto. Under a general heading comprising all instances of external otitis, chronic and acute, and covering dermatitis and eczema of the auditory canal and auricle, I have grouped no fewer than 90 cases; while in addition to these a diagnosis of furuncle was established in 40 others.

Of foreign bodies found within the auditory canal or tympanic cavity there were in all 17 instances. Traumatic perforations of the membrana tympani were clearly proved to exist in 5 ears, and were suspected from the anamnesis and lesions observed in 6 ears. Of fracture of the temporal bone leading to aural symptoms and lesions there were 3 instances. In 4 cases a well-established, and in 2 cases a suspected, diagnosis of tubercular purulent otitis media was made. In 3 instances a special diagnosis of "Ménière's symptoms" was entered, while these symptoms were recorded as present in 8 cases otherwise classified.

Other rarer diagnoses were the following: Otalgia and dentition, 9; otalgia and pharyngitis acuta, 2; hæmatoma auris, 2; epithelioma auriculæ, 1; fibroma auriculæ, 1; erysipelas, 1; recurrent dermatitis from frost-bite, 1; incised wound of auricle, 1; cystic abscess of auricle or auditory canal, 9; mumps, 1; microtia, 1; deaf-mutism, 5; otitis interna, 7.

The presence of symptoms indicative of implication of the mastoid cells was noted in the history of 21 cases.

Adenoid vegetations in the pharynx vault were unmistakably found in 33 cases, and were doubtless present in many others not so carefully examined. Aural polyps of sufficient size to deserve special mention were found in 56 cases.

In the matter of operations done, the department makes a very respectable showing. Thus, paracentesis of the drum-membrane was performed 54 times in 49 cases; the removal of one or more aural polyps was resorted to in 38 cases (such removal being almost without exception effected by snare evulsion); abscesses were incised 13 times in 12 cases, furuncles in 20 cases; in 8 cases a "Wilde's incision" was made; in 3 other cases the mastoid cells were opened by drilling.

As evidence of the distribution of the work between my assistants and myself, I would say that out of the total number of 1,500 clinical histories I find but 345 recorded wholly in my own handwriting, and only 38 others in which my notes appear on the books; and that our practice has been to have the man who saw and treated the patient record himself the lesions observed and the treatment followed. Many cases not recorded by me were from time to time referred to me, yet such were not considered as cases under my especial care. So, too, with regard to operations. While it was my duty to see that they were competently performed, and neither they nor the records were unreservedly committed to other hands, yet I aimed at training all my co-workers to a point rendering them competent to do any kind of clinical work, and as soon as I was satisfied of their ability, gave them all kinds of work to do. They were generally men who, on entering the service of the clinic, were already fitted to bear a considerable load of responsibility. Two of the operations of drilling the mastoid cells were performed by Dr. F. N. Lewis, who was then our senior assistant and fully competent to do this operation, as was proved by the good result obtained in both cases. The third case I did myself at the New York Eye and Ear Infirmary, and the operation did not save the patient's life. (This case, which was, to be sure, one of especial severity and gravity, and remarkable in many respects, I have reported in full before the American Otological Society in July last.)

As illustrative of what has already been said regarding the fulness of clinical notes, which has constituted an especial feature of our work, I would here add that in look-

ing over the history-books I find no fewer than seventy-one carefully made pen-and-ink drawings of the lesions observed, in addition to such as are merely diagrammatic.

A few words in regard to our general methods of treatment may be of interest to some readers.

The important etiological relations existing between lesions of the naso-pharyngeal region and those of the ear are never forgotten in our department, and we frequently seek, and are often greatly aided by, the co-operation of the adjoining Throat Department in our efforts to help those who apply to us for relief. Our experience has abundantly proved the value of a prompt resort to paracentesis in cases of acute otitis media; and also of the "Bacon's artificial leech," and of an early dose of calomel in these cases and in acute inflammatory affections of the auditory canal and auricle. The special lesions and special history of each such case are of course the determining factors leading to choice among these remedial agents, rather than the bare determination of the diagnosis, and nobody at all familiar with aural practice will expect me in this place to attempt the laying down of rules for guidance in regard to these matters of detail. We do not allow ourselves to be bound by, and subservient to, so-called "systems of treatment" and rules, while endeavoring to pay due regard to our own experience and that of others (especially of Professor Buck, the head of our department), in our choice of means to an end.

In chronic purulent otitis media, powders and astringent ear-drops are used in suitable cases, the former in small quantity, the later rarely; the douche is chiefly, and often exclusively, relied on in combating such cases, and powdered medicaments in particular are more sparingly and much less frequently used at present than they were in the early days of the clinic. It should be unnecessary, but it may be well to add one more remark concerning our treatment, viz., that the relief of the patient from suffering is made our chief object, and severe and painful remedies are not employed where there is reasonable ground for hope that less radical means will accomplish this object.

The growth of the clinic is shown in the subjoined table, giving the number of new cases applying in each quarter of a year from the opening of the dispensary to and including May 24th, anno currente:

New Cases in each Quarter.

1.	Jan. 1,	1888,	to	March	31,	1888	16
2.	April "	"	"	June	30,	"	112
3	July "	"	"	Sept.	30,	"	140

With rare exceptions our *clientèle* have been drawn from the extensive tenement-house district lying to the north, west, and south of the clinic; and we have been struck by the large percentage of such cases supplied by the blocks lying in the immediate neighborhood of the building itself.

Finally, I cannot in justice conclude this *resumé* of work done without expressing my indebtedness to the gentlemen who have been my faithful and painstaking co-workers in building up and in keeping up the clinic, and in order to do this the more explicitly I subjoin their names and periods of service.

Dr. Gorham Bacon, Attending Aural Surgeon at the New York Eye and Ear Infirmary, was my sole fellow-laborer at the start, and from January 1st to some time in May, 1888, he divided with me the hard work of setting the infant clinic on its legs. On his resignation, in May, 1888, Dr. F. N. Lewis took his place, and served until called away by more important duties in March of this year. Dr. William Cowan began work in June, 1888, and is still serving. Dr. Robert Lewis joined us in October, 1888, and is still on our staff; so, too, are Dr. N. S. Roberts, who began work in March last; Dr. W. Eyre Lambert, who began in May, and Dr. J. L. de Victoria, who enlisted more recently, being appointed *ad interim*, pending the next meeting of the College Faculty, by the Board of Managers of the Clinic. Each of these gentlemen was selected because he appeared competent to do the painstaking and time-consuming work, calling for skill and for patience, that is demanded by our department; each of them has proved by his work that he was well chosen.

Clinical Department.

TWO CASES OF STENOSIS OF THE LARYNX —RAPID TRACHEOTOMY, DIVULSION, RECOVERY.

By EMIL MAYER, M.D.,

ASSISTANT SURGEON, NEW YORK EYE AND EAR INFIRMARY.

CASE I.—James M——, aged twenty-five, Italy, barber, peared at the throat clinic of the New York Eye and Ear Infirmary, October 29, 1884, for treatment. Patient has intense dyspnœa, which has been growing worse within the past few days. Voice thin and stridulous. Save that his history is a specific one no connected history can be elucidated. His pharynx was one mass of cicatrization. The induration in his larynx destroyed all semblance of the natural parts and left but a small chink for breathing. Immediate tracheotomy was advised, and without an anæsthetic. Patient positively refused to do without the anæsthetic. As he required immediate help, he was anæsthetized and the operation undertaken. The dissection was more than half completed when respiration ceased and cyanosis set in. The trachea was firmly seized and with one incision the operation was completed; air rushed into the lungs and respiration became re-established.

From this time on patient did well, and at the end of eight weeks discarded the tube and the wound healed. During this time large doses of iodide of potassium were given. Much of the intralaryngeal induration had subsided and there was ample breathing space. There was no choice in the manner of operating, cocaine had not been announced as a local anæsthetic and the operation was imperative. Without it he must have died a horrible death within a short time.

There was no unusual hemorrhage.

CASE II.—Mr. W. A. Y——, aged thirty-eight, printer, appeared at clinic July 5, 1890. His condition was one of great distress. His voice had a harsh, metallic sound and was feeble, and the dyspnœa was intense. He dates his trouble as resulting from an exposure to cold in the early part of February of this year. He first noticed a dry spasmodic cough, his inspirations were noisy, and his breathing was difficult at night only. This latter soon became noticeable in the day. He continued at his work and his sleep was fair. He gradually grew worse and within the past two weeks his rest has been greatly disturbed, waking with a choking sensation. His inspirations have become noisy and he is an object of universal attention wherever he goes. He has attacks of great dyspnœa of short duration now. His deglutition is not impaired, face has an anxious look, appetite good, bowels regular. Present condition: Respirations 24; inspirations noisy; cough spasmodic and dry; pulse 100 and not strong; no pulmonary or cardiac trouble; temperature normal; gives a specific history; pharynx normal; larynx in a condition of subacute congestion; the vocal cords are seen pink in color and do not move in phonation; a very narrow chink about one line in width is discernible.

A small-sized Schrötter's tube was introduced, under cocaine anæsthesia, between the vocal bands and then

withdrawn. The cause of the stenosis was now apparent. There was a firm crescentic band across the trachea, nearly filling its diameter and directly below the cords, preventing the separation of the vocal bands. The tube has separated the cords and torn the membrane. Tubes of larger dimensions were introduced at intervals of two days for the next three weeks, the increase in size being gradual. Their introduction caused no trouble beyond local irritation which quickly subsided. At the end of three weeks, the largest tube having been easily introduced, there were but a couple of small flaps remaining. The largest tube was now introduced weekly and now (Aug. 30) there is no sign of any obstruction. He was relieved by the first introduction of the tube, and within three weeks of the first application no evidence of dyspnœa was apparent, he slept well and returned to his work. His medication consisted of large doses of iodide of potassium. He was seen by Dr. Morris J. Asch, who concurred in the diagnosis and treatment. The tube was first used as a means of diagnosis and every precaution taken to prevent injuring his larynx. The patient was watched and if necessary tracheotomy was to be performed. He bore the dilatation well, however.

A case similar to this, in its pathological condition, was reported by Dr. Asch to the American Laryngological Association in 1887, and is to be found in the "Transactions" of that year. This case was that of a young lady who had "at the level of the cricoid cartilage, and encircling the opening of the trachea, two pale, thick, shining swellings, united posteriorly by a membranous expansion, and leaving the anterior wall free, which diminished the opening of the larynx to a third of its natural size." The treatment followed was, nicking the membrane by means of Whistler's laryngotome and then divulsion by means of long laryngeal forceps, opening laterally; later, Schrötter's tubes were used. Recovery was complete. The patient was under my care then, under the direction of Dr. Asch.

In the discussion which followed (*loc. cit.*) the objection made was that the results of treatment by dilatation alone were not apt to be permanent. I have seen the young lady here referred to within the past six months. There has been no return of her tracheal trouble and over four years have elapsed since she was under treatment. In this case the trouble was evidently tubercular in its origin.

The advantage of dilatation lies in its bloodless nature and the rapid results obtained. The ordinary O'Dwyer tube could not be tolerated by either patient, although it is likely that the newer and hard rubber tubes might be better borne. The Schrötter tube is of hard rubber, hollow in the centre with several openings at the laryngeal end. It is the shape and length of a male urethral sound and in width varying as the sounds. It is readily introduced with the aid of the laryngeal mirror. The patient soon becomes accustomed to its use. It was not necessary to leave the tube *in situ* more than one or two minutes, although Gerhardt, Chiari, and others report cases where the patients permit the tubes to remain *in situ* for twenty minutes, introducing them themselves.

Dilatation should be gradual, as undue violence may occasion inflammation and thus render an artificial opening necessary. Another advantage of this tube is that deglutition is not interferred with during treatment.

238 E. 116TH STREET.

ESSENTIAL HYDROPS.

BY MARCELL HARTWIG, M.D.,

BUFFALO, N. Y.

THE public speak of hydrops, or dropsy, as if it were a disease, while physicians regard it as a symptom of disease. Is it possible for such a condition to exist as an idiopathic disease? I submit herewith the history of a case and request discussion and information of similar cases which members of the profession may have seen. With a large general practice and sixteen years' experience I have not seen a like case, nor can I find any literature on the subject. To some of the profession it might appear that the case has been reported too soon after recovery, but the reason for so doing is that if I were to delay the publication important details might be forgotten. Dr. Schroeter, in Buffalo, can corroborate my statements.

Miss G——, a girl of previous good health, sixteen years of age, of large, well proportioned frame. She was pale, and menstruation was irregular and scanty. Father and mother living and enjoy good health. Two near relatives of the father died of consumption. The patient had a general feeling of sickness and lay in bed two days, but was forced to go to work again. She could not stand the effort and went to bed again with œdema of the eyelids and feet, and an increasing fulness of the abdomen. Some fever is said to have been present for a week.

On July 1st I was called, and found the following status: Virgo intacta; abdominal dropsy reaching in its distention to the level of the navel, and fluid moving to the sides only slowly upon change of the position of the body, œdema of the legs and face; hydrothorax duplex on the right side much higher than on the left; lungs and heart normal; no albumin found in the urine; temperature, 103° F.; liver and spleen also showed nothing abnormal. The accumulation of the abdominal fluid displaced the under surface of the liver above the lower border of the ribs. Treatment consisted of quinine in sufficient doses to overcome a possible malarial infection, afterward digitalis with iodide of potassium, and later acetate of potassium, spirit of nitrous ether, and fluid extract of buchu, occasionally a saline purge, although the bowels were inclined to be loose. On July 10th I tapped the abdomen, and convinced myself of the correctness of my diagnosis of hydrothorax by withdrawing a hypodermic syringeful of clear watery fluid. The ascitic fluid present amounted to about five quarts. It was clear, light greenish in color, and deposited upon standing a somewhat coherent coagulum with a reddish tinge. The following day the temperature began gradually to fall to the normal, while the fluid in the thorax began to diminish and the ascites did not reappear.

For a few days if seemed as if the lowest parts of the abdomen gave a duller sound on percussion, but if any reaccumulation took place it disappeared, and on July 22d the girl was apparently well recovered from the fever, only weak from her previous disease. The pulse reacted readily upon slight excitement.

The case is one of essential hydrops, a condition which may have been overlooked by authors, or if described its publication is not known to me. Some may regard this condition as a sequel of scarlet fever, but no eruption or throat trouble preceded the case, and the urine was several times found to be absolutely free from albumin. A tubercular peritonitis could be thought of; but after the ascites disappeared there was no thickening of the abdominal walls; besides, the thoracic effusion would probably not have vanished spontaneously. Some symptoms would have been found in the lungs, at least, in a case of tuberculosis, but nothing was detected upon very careful examination. A monocyst is excluded by the continued fever and the general spread of the dropsy.

How can such a hydrops be explained? I do not venture a hypothesis, though the continued low fever would indicate some inflammatory process. Is it possible that this was a condition of capillitis venosa generalis, or is the lymphatic system to be accused? The glands were nowhere swollen.

The case occurred in private practice. Exact measurements of the quantity of urine were impossible, but the amount seemed to have been sufficient throughout, somewhat larger in quantity after the tapping. The case resembled a renal dropsy, but this it could not be, albumin being absent and the fever continuing too long for acute nephritis.

A liver ascites would not be accompanied by hydrothorax or œdema of the face. Myxœdema can be excluded from the possibilities, as the case showed none of the usual symptoms of this disease, and nothing remains for us but to consider the case described as a new disease—essential (or inflammatory?) hydrops.

ANOTHER CASE OF SPONTANEOUS GANGRENE IN A CHILD.

By D. S. MADDOX, M.D.,

MARION, O.

The two interesting cases of dry or spontaneous gangrene occurring in children recently reported in the Medical Record, respectively by Dr. W. H. Hubbard, of Marion, Ind., and Dr. T. C. Wallace, of Cambridge, N. Y., prompt me to relate a fatal case of this character which came under my observation a few years ago while practising in a remote country district in the State of Indiana. As I have no written record of the case further than an old ledger, which supplies me only with dates, I am compelled to rely solely on memory for the details.

October 19, 1885, Mr. S—— brought his little boy, a child between five and six years of age, to my office for the purpose of having me look at "a black spot on his foot." Examination revealed a dark-colored patch, possibly as large as a silver quarter, over the metatarsal joint of the great toe, whether of the right or left foot I cannot now recall. The child had always been healthy and no history of injury could be elicited. As a topical application a weak solution of carbolic acid was ordered and the foot enveloped in cotton batting. The patient living at a distance of several miles, I requested the father to report the progress of the case to me in a day or two. At the end of two days he called and told me that the child was comfortable and that the gangrene had spread but very little.

October 23d, I saw the patient at his home and found that the disease had spread considerably. In other respects the child appeared to be in good condition.

On October 25th, six days from the date of my first inspection of the foot, I again went to visit my patient. As I dismounted from my horse in front of the log-cabin, my ears were greeted by cries of distress from within. Hurrying into the cabin I found the entire family grouped about the bed on which lay my little patient in the death agony. On looking at the diseased foot I found it black and shrivelled clear up to the ankle-joint.

I learned that the child had, while sitting on the floor playing, an hour before, fainted, but soon revived and resumed his play. A few minutes before my arrival he again fell back unconscious, and died in the manner above stated. All the authorities agree that spontaneous gangrene is of extremely rare occurrence under the age of ten years, but possibly if all the cases that do occur in children could be collected, statistics would scarcely warrant us in making such free use of the term *senile* as we are accustomed to make in the consideration of dry gangrene.

A RAPID CURE OF TONSILLITIS.

By A. S. HUDSON, M.D.,

STOCKTON, CAL.

In the year 1872 a German woman, twenty five or thirty years of age, was seized with a painful sore throat, or quinsy. She came to the writer for relief. Being poor and obliged to do her own housework, she trembled at the prospect of a long period of disability. She was given fully two-thirds of a grain of morphine, with ten drops of Norwood's tincture of veratrum viride, which was taken on going to bed.

Knowing our text-books furnished no remedy or plan of treatment that would arrest the course of inflamed tonsils, and taught no way to prevent suppuration thereof, you can judge of my surprise the next morning, after breakfast, to see the patient well and up, and about her housework. She was cured, and had no further treatment.

Some months, or a year thereafter, a robust colored man, a porter on the Pullman cars, was seized with a sore throat at Ogden. His run on the Central Pacific Railroad from thence to his home in Oakland took two days. The writer saw him on the morning of the third day. He had fever, a flushed face, with tonsils swollen and painful as usual.

He was put upon the following:

Norwood's tincture of veratrum viride...	30 drops.
Sulphate of morphine.....	1½ grain.
Distilled water.....	6 drachms.

Of this, one teaspoonful was to be taken every hour for two hours, and then every two or three hours, as needed.

This is five drops of veratrum and a quarter grain of morphine in a teaspoonful of water as one dose. The next morning this patient was found to be up and dressed; he had had his breakfast and was smoking his cigar, his throat being entirely well. This, to my great delight, was a confirmation of the preceding case, described above.

Since then, the writer has seen no case of pure tonsillitis that has not yielded at once to the above treatment in the same brief time—that is, from eight to twelve hours, and the patient is an invalid but one day after the beginning of treatment.

If there is any meaning in the common word "cure," that meaning centres in these two words, viz., veratrum and morphine for tonsillitis.

How it is with other medical men I know not, but for me, in a practice of half a century, I know of no drug or drugs which have the power to control inflammation equal to these agents. They harmonize well together. The liability of nausea to follow the use of either of them alone is greatly modified by their combination. Hence there is reason to believe they exert therapeutic powers, when in conjunction, that are absent or lost when used separately.

The last case of quinsy the writer had to manage lasted five or six days. But the subject insisted in being treated while attending to business. She was medicated at night, and what relief that period brought was lost during the day while she was teaching music. At last, seeing she could not get well while on her feet, she lay by for twenty-four hours, took the medicine, and fully recovered without the formation of abscess.

DISLOCATION OF THE HUMERUS INTO THE AXILLA IN A CHILD.

Dr. A. R. Brackett, of Nashua, Ia., writes: "I had recently the privilege of meeting with what I believe to be a rare accident, viz., dislocation of the humerus into the axilla, occurring in a child of two years. The flattening of the shoulder and Hamilton's straight-edge test established the diagnosis without difficulty. The reduction was made under chloroform by manipulation, the head of the bone returning to the glenoid cavity with the orthodox snap.

"The mishap was due to the sudden lifting of the child by the extended arm. Dr. Gross states that he never had seen a case under twelve years, and other authorities at my command coincide as to its rarity."

More Hydrophobia.—St. Paul has a new hydrophobia fad. A Chicago paper states that a number of people in that city believe themselves to be suffering from hydrophobia convulsions in consequence of drinking the milk of a cow that had been bitten by a mad dog.

Progress of Medical Science.

The Rôle of Uric Acid.—According to Dr. William Roberts the formation of uric-acid concretions and calculi is really to a large extent independent of the absolute amount of uric acid present in the urine. A person may be excreting a relatively large amount of the acid, and never be troubled by anything in the nature of a gravel; while, on the other hand, with an abnormally small proportion of the acid in the urine, his life may be made a misery by the constant formation of irritating concretions. In other words, it is the deposition of the uric acid, and not its excretion, that determines its pathological significance. It was the conception of this fact that led Sir William Roberts to undertake a series of researches with the object of ascertaining the conditions that led to the too ready precipitation of the acid in certain cases independently of its presence in excess. The explanation of this phenomenon is that, in normal urine, uric acid is found in the form of *quadurates*, a super-acid combination first discovered by Bence Jones. These quadurates have the remarkable property of being not only soluble in normal urine, but of being decomposed and setting free the acid in the presence of water. This takes place in urine under ordinary circumstances in the course of three or four days, but the rapidity with which the whole of the uric acid is set free varies greatly in different specimens of urine, whether from different persons or from the same person at different periods of the day. The fact that the quadurates resist the influences at work for so long a period led the author to infer that the urine must contain ingredients which inhibit or greatly retard the action of the water in the urine upon the quadurates. The most important factor in this respect has been shown by him to be the saline constituents, and secondly, of the pigments in the urine. These results explain with a clearness that has not before been approached, the prevalence of acid calculous formations among peoples in countries and districts, and among classes of our own population in which, for any reason, the diet is unduly poor in saline matter. In certain districts in India, for instance, where salt as an article of diet is more or less of a luxury, acid calculi are extremely frequent, and among the children of the working classes in this country the use of food stuffs poor in mineral constituents may account for the preponderance of calculus among them as compared with the children of parents higher up in the social scale. So far as India is concerned, the lack of salt as a condiment is enhanced by the marked poverty of rice in mineral constituents. It is not denied that the nitrogenous qualities of the diet does influence the production of uric acid, but, as we have already pointed out, this is of secondary importance, because meat contains a large proportion of salts, the effect of which is to tend to keep the acid in solution. The well-known immunity of sailors from calculous affections, notwithstanding a dietary rich in nitrogenous matter, is presumably due to the large proportion of saline materials contained in the salted meat at their disposal. There is a popular idea that the ingestion of sugar is associated with a hyper-production of uric acid, but neither clinical observation nor experiment at all confirms this view. That the nitrogenous constituents of the dietary are not alone, or even principally concerned in the formation of the acid, is evidenced by the fact that the proportion of the acid in the urine of carnivorous animals is a thousand times less than that in urine of certain small birds and insects which feed exclusively on articles drawn from the vegetable kingdom. The practical outcome of these researches, which we have merely outlined, is, as stated by Sir Alfred Garrod, that the great object in the preventive and curative treatment is to correct the conditions which bring about the changes in the urates which lead to the deposition of the insoluble acid. This fact may prove the *point de depart* of an improved method of dealing with a very obstinate and painful pathological condition, and it almost justifies the hope that, at some time in the near future, the physician may be enabled to forestall the surgeon, and by rendering the formation of this class of concretions a rare event, to dispense with the skill and ability in this particular department with which the name of Sir Henry Thompson has for so many years been honorably associated.—*Medical Press.*

Dangers of Hypnotism.—At the late meeting of the British Medical Association, Dr. Norman Kerr, of London, introduced the subject of hypnotism. He said that he accepted practically all the alleged hypnotic phenomena as facts. But in hypnosis, after close watching, he saw only a distorted cerebral state, an abnormal physical condition, with exaltation of receptivity and energy. Was hypnotism a desirable and justifiable remedy? Several considerations must be taken into account in answering this question: 1. Only a limited number of persons were susceptible. 2. The after-effect was a disturbance of mental balance, a dissipation of nerve energy, and nerve exhaustion. Frequent repetition was apt to cause deterioration of brain and nerve function, intellectual decadence, and moral perversion. 3. Hypnosis was a departure from health, a diseased state. 4. Hypnosis was a true neurosis, embracing the lethargic, cataleptic, and somnambulistic states. Thus, if a disease were cured by hypnotism, this would be only by substituting another disease. The suffering was sometimes temporarily assuaged by hypnotic suggestion, but the underlying disease was not necessarily cured by hypnotic anæsthesia though evanescent oblivion might be secured. 5. The lethal power of the morbid disorder, of which the pain was a merciful if unwelcome messenger, was in most cases increased. The few cases he had seen apparently benefited would probably have yielded to ordinary treatment; but the patients resisted or were passive to that, while they looked forward to, believed in, and gave themselves up to the mesmerizer. 6. The dangers of hypnotism were very great. Each séance might bring the hypnotee more under the control of the hypnotist, ending often in the complete submission of the former to the will of the latter. A jelly-fish slavery, without mental or moral backbone, was infinitely worse than days of pain and nights of agony. There were many wrecked lives through mesmerism. 7. An elective and subtle activity, ending in disaster, might develop between operator and operated upon. 8. In the lethargic and cataleptic states criminal assaults had been committed by medical men, who had been convicted and punished. In the somnambulistic state subjects had been compelled by the operator's behest to commit crime. So serious were these evils that French surgeons had been prohibited from practising hypnotism in the army and navy. 9. It is not desirable that the control of any one's thought and actions should be in the keeping of a fallible fellow-mortal.

In view of all these possible dangers, Dr. Kerr could not understand why medical men in family practice should have been incited to hypnotize patients of both sexes and all ages in the daily round of domiciliary visiting. He strongly deprecated public mesmerism—medical, philanthropic, or commercial—as degrading and disgusting, and particularly censured the medical patronage and endorsement thereof.

Removal of Micro-Organisms from Water. — Dr. Krüger, considering the fact that more bacteria are usually present in rivers than in lakes, notwithstanding that lakes themselves in many cases are more or less polluted by rivers passing through populous towns, believes that this rapid decrease in the number of organisms may very possibly be due in part to the action of direct sunlight, but in the main to the tendency of water in a comparatively undisturbed state to deposit and precipitate. He therefore carried out a number of experiments with a view to determine how far the removal of organisms was brought about by the mere mechanical deposition of inert matter

and also by precipitation as a result of chemical action. The mechanical precipitants employed, all in a state of fine powder and sterilized, were alumina, brick dust, clay, chalk, sand, coke, and charcoal. Water obtained from an ordinary service-pipe was impregnated with a liquid containing a bacillus growth of a species incident to tap-water. This was divided into two portions — one for precipitation with the inert substance, and the other was untreated for the sake of comparison. Experiments were similarly carried out in which precipitation was obtained as a result of chemical action such as is brought about by the addition to the water, containing naturally lime, magnesia, etc., substances like wood-ash, sulphate of alumina, and slaked lime. The general conclusion come to by the author from the results obtained is that undoubtedly large numbers of bacteria are carried down by inert substances merely sinking in the water, but that the action is very considerably increased when, in addition to mechanical deposition, a chemical precipitation also takes place. The corollary is evident—inert substances do mechanically assist in the precipitation of micro-organisms, but preference should be given to chemical treatments.—*Druggists' Circular.*

On the Treatment of Metrorrhagia.—According to Dr. Edis, where the hemorrhage results from constitutional or general conditions it is not always wise to attempt to check the flow at once, unless it is producing such an effect upon the system as to suggest the expediency of arresting it at all hazards. In certain cases of heart disease uterine hemorrhage, in place of aggravating, seems to relieve the cardiac symptoms, and should not, therefore, be hastily repressed. Strophanthus, digitalis, and aconite here prove most useful. Where the action of the liver seems to be at fault, attention to diet, abstention from alcohol, and the administration of a few grains of calomel, blue mass, or eunonymin, followed by a brisk saline aperient, will probably be indicated. If albuminuria be present, or if the kidneys seem to be at fault, encourage vicarious action of skin and bowels by means of diaphoretics and purgatives, and follow out any other indications suggested. In cases of menorrhagic chlorosis, bromide of potassium in half-drachm doses has proved of service, iron with strychnine being given between the periods, and attention being also given to ordinary hygienic details, to avoidance of tight-lacing and of physical overwork. It is well to remember that hæmophilia, scurvy, malaria, from residence in damp or marshy districts, lead-poisoning, and other unusual conditions will occasionally explain the presence of metrorrhagia. The mere recognition of the cause will be at once a suggestion as to the proper course of treatment.

Where uterine hemorrhage persists, notwithstanding the employment of constitutional measures, and there is no apparent local cause to account for it, we should without further delay dilate the cervix uteri and explore the interior of the uterus. Numerous instances have been recorded of patients dying from uncontrollable hemorrhage, where a *post mortem* examination revealed the existence of some intra-uterine growth, such as a polypus or submucous fibroid, retained product of conception, or fungoid condition of the endometrium, which could readily have been removed or dealt with had appropriate measures been adopted in time.

The insertion of a sponge-tent into the cervix uteri arrests the hemorrhage for the time being, and facilitates subsequent exploration of the uterine cavity. As to any risk or reflux through the Fallopian tube, as sometimes spoken of, it is a mere visionary objection, and need not deter us from employing dilatation in suitable cases. Plugging the vagina is a very unscientific procedure, as well as being unsatisfactory and inefficient. It should seldom, if ever, be resorted to.

It would clearly be impossible in these brief remarks to indicate in detail the methods of local treatment, such as curetting for villous endometritis, removing polypi, operating for cancer, the use of electricity in cases of myoma, the best method of dealing with cases of incomplete abortion, or replacing an inverted uterus. If we have once clearly made out the indications for treatment the remainder is merely a matter of detail. But now and again instances occur where no assignable cause, either constitutional or local, can be made out, and where remedies fail to restrain the hemorrhage. In such cases the hot vaginal douche may prove of service, or even washing out the uterine cavity with hot water through a double-current catheter, provided the cervix be patulous enough to admit it. Should this fail it may be considered requisite to wash out the interior of the uterus with a strong solution of iodine or of iron. As a *dernier ressort*, the insertion of a sponge-tent into the cervix uteri may be effected.

The reliable remedies at our disposal for checking or arresting uterine hemorrhage are really very few. Ergot is unquestionably one of the most potent; hydrastis Canadensis is a valuable agent and far too little generally known. In cases of myoma it often proves of service when ergot has failed. Hamamelis, which forms the basis of the American nostrum, hazeline, is sometimes useful. Quinine and strychnine, alone or in combination, often succeed in checking or arresting hemorrhage in those cases where the system is much depressed from repeated or prolonged losses. Bromide of potassium in cases of ovarian irritation, and even in hematocele, possesses the power of checking hemorrhage and is equal, if not superior, to any remedy we possess. Chlorate of potassium, in combination with ergot, has lately been strongly recommended. Opium is beneficial in cases where the loss has already been severe. Sulphuric acid and opium formerly were, and still are, with some practitioners, favorite remedies; also, acetate of lead and opium in the form of pill.

The ordinary astringents, such as gallic and sulphuric acids, have really very little influence in restraining hemorrhage, and are far too often relied upon. Iron is often of much benefit in those cases where the loss has been very profuse, as in myomata, and where the blood has become so attenuated as to pass readily through the capillaries. Digitalis, in combination with iron, proves most valuable in cardiac complications.—*The British Medical Journal.*

Self-infection.—Dr. Von Szabo defends the view that the organism itself destroys the microbes ordinarily present in the genital canal, and that hence the healthy lying-in woman is to be regarded as aseptic. The practical inference is that sterilization of the parturient canal is at least supererogatory, if not positively injurious. The steady diminution of puerperal morbidity since the introduction of antisepsis, the grouping of puerperal diseases, and the direct variation of their frequency with the number of examiners all discredit the assumption of self-infection. Clinical observation of lying-in patients bears in the same direction. Fever in childbed more frequently follows injuries of the perineum and vaginal orifice than those of the cervix. If fever depended on the micro-organisms normally present in the vagina this difference should not exist. Contamination of wounds of the external genitals occurs more frequently in childbed from pyogenic bacteria, that so easily accumulate in clinics, than in labor from microbes introduced by efforts to protect the perineum. That infection is so often observed with retained membranes Von Szabo explains, not by migration of pathogenic microbes by means of the pendent membranes, but by imbibition by the uterus of pyogenic material from the vagina during the negative pressure of relaxation following contraction. Manual removal of retained membranes is to be counselled, for it puts the lying-in woman in a more favorable condition than if their removal be left to nature. Street labors and precipitate labors generally are not more exempt from febrile sequelæ than labors in which repeated examinations

have been made, presumably because unfavorable surroundings promote infection from without. Notwithstanding the temporary suspension of vaginal examination during unfavorable hygienic conditions, the morbidity still remains higher than normal—accumulation of septic material in the clinic facilitates infection in childbed, as well as in support of the perineum. Von Szabo asserts also that puerperal morbidity is not diminished by vaginal irrigation before labor. The essential thing in obviating infection is "subjective disinfection," and this is best accomplished with sublimate solutions.—*Occidental Medical Times.*

Palpable Kidneys.—Dr. Kuttner has published a series of articles in the *Berliner klinische Wochenschrift* on those cases in which the kidneys are accessible to the touch. His observations are noticed as follows in the *Edinburgh Medical Journal*, August, 1890: Kuttner distinguishes four principal forms in which the kidneys are accessible to bimanual palpation. 1. The kidney shows a clearly demonstrable respiratory mobility with unimportant amount of displacement. 2. Or it shows a dislocation of the first degree, that is, one-third, one-half, or two-thirds of the organ can be felt; it is mostly mobile during the respiratory act, can be pushed out of place by the hands, and is dislocated, more or less, forward. 3. Or it shows a dislocation of the second degree; the kidney can be felt in all its extent, is easily pushed about, moves with respiration, lies near the anterior belly-wall, or can easily be brought thither. 4. Or the kidney is dislocated and fixed in its abnormal position.

Many of such dislocated and fixed kidneys are congenital and of slight clinical importance, but often this condition is acquired when a mobile dislocated kidney becomes fixed by the development of local inflammatory processes. To understand how one degree can be evolved from the other, it is requisite to have a clear view of the etiological movements which condition the origination of palpable kidneys. In the first line we have to take into account the factors which are in a position to loosen or destroy the connections of the kidneys, and so bring them into other than normal relations to neighboring organs. A few authors suppose that the disappearance of the fat of the capsula adiposa renis is a likely cause. Experience agrees with this view; movable kidneys are frequently met with in the progress of diseases attended by a general loss of fat, as in phthisis, carcinoma, etc., or in acute diseases with high fever, as in typhoid, malaria, etc. Should the fat of the adipose capsule disappear, and be replaced by a slack, wide meshed connective tissue, the kidney loses its firm support and sinks downward by reason of its weight. The tolerably equable pressure it formerly exercised on the peritoneum becomes one-sided and downward, the elastic peritoneum yields and stretches; a sort of renal mesentery is thus gradually formed, and allows the organ to make similar excursions to those we see normally in organs furnished with a lengthy mesentery. To complete this condition time is required. In proportion as the fat of the adipose capsule vanishes, and the kidney assumes a lower position, its respiratory excursions increase in extent and become more and more accessible to the palpating fingers. While the kidneys sink downward, they recede gradually from the direct influence of the diaphragmatic contractions, and on the right side become affected by the respiratory depression of the liver, which still further continues the dislocation downward. Perhaps this is one reason why right-sided movable kidney occurs most frequently. As Cruveilhier has pointed out, tight-lacing is also a powerful factor in the production of floating kidneys. Of not so much importance, in the author's opinion, are frequent pregnancies, abortions, pendulous abdomen, and the supposed causation of hyperæmic swelling of the kidneys occasioned by menstruation (as consequence of the connections between the plexus ovaricus and plexus renalis) as has been asserted by several authors. Occupation, the doing of hard work or none at all, does not seem to have any influence on the production of movable kidney. Traumatisms, such as falls, blows, gymnastic exercises, etc., have also been credited with bringing about this condition. Probably the mobile kidney was present before the accident which was supposed to originate it had happened. All that has been advanced as causal does not explain the floating kidneys of children and young girls. All the causes cited can only be "opportunity causes," which lead up to movable kidneys or make movable ones more mobile only in a certain predisposition, but of themselves are not able to remove a kidney from its normal place permanently or temporarily, and give to it a certain amount of mobility. The frequency of this condition, which was once considered an anatomical curiosity, is much greater among women than men; out of 667 cases tabulated from various authors, 584 occurred in females and 83 in males. It may happen at any age, the greatest number of cases happening from thirty to forty years. It occurs oftenest on the right side; out of 727 cases, 553 were right, 81 left-sided, and in 93 both organs were affected. If the causes of ren mobilis are obscure, so also the symptoms occasioned by it are uncertain and doubtful. Sometimes no inconvenience is felt; at others pains of a dragging, pinching, and boring character are complained of, limited to the affected side or radiating to the other, or to the loins and between the shoulder-blades: they are paroxysmal, brought on by slight exertion, or may take on the form of neuralgiæ, especially sciatic and intercostal. The annoyances increase during menstruation. Many patients are highly nervous, hysterical, and hypochondriac. The urine is sometimes albuminous and (rarely) bloody. Disturbances of digestion are more frequent; but it is doubtful whether the relation is causal or mere coincidence. Constipation may be caused by the mechanical pressure of the displaced kidney. The occurrence of icterus is explicable by mechanical functional disturbances of the gall-bladder, but the author has never seen this complication in any of his cases. Patients with movable kidney are subject to sudden attacks of abdominal pain, feeling of anguish, vertigo, vomiting, and fever. The cause of this has by some been attributed to strangulation of the kidney in the surrounding connective tissue and peritoneum, giving rise to a more or less circumscribed peritonitis; others blame torsion of the renal vessels, especially the veins, and consequent acute congestion; others attribute it to intermittent hydronephrosis. Slighter urinary disturbances are relatively frequent, colicky pains during micturition, frequent desire to urinate, and slight polyuria; these are generally unimportant and transient. As authors differ about the etiology and symptomatology of this disorder, so they deviate from each other as to its cure. Some see the only possible cure of ren mobilis in its extirpation, some in nephrorrhaphy, and others object to all operative interference. The author would limit himself to nephrorrhaphy in the very worst cases threatening life and destroying all comfort. Properly constructed bandages are useful, and most in cases accompanied by pendulous abdomen. Narcotics and narcotic salves, poultices, and so on, may be needed for the pains, and the stomach disturbances must be treated specially.

Intestinal Antisepsis.—To render innocuous the pathogenic organisms of the intestines, attempts have been made with drugs administered by the mouth or rectum. By the first method only those remedies are indicated that will pass through the stomach unchanged. Calomel is an agent of this class, but while serviceable in simple fermentative conditions, it is impracticable in infection of long duration. Bouchard has used large quantities of pulverized carbon in typhoid fever; naphthalin, iodoform, and salicylate of bismuth have also been recommended. These agents possess a certain antiseptic influence on the contents of the alimentary canal, but on the intestinal wall their action is *nil*, which fact receives confirmation in the

treatment of typhoid fever. The intestinal antiseptics require heroic administration, and aside from toxicity, they are absorbed in the stomach and altered in their chemical constitution before attaining the desired site. For this reason Cantani considers their exhibition per rectum as the proper method. Repeated experimental investigations show that intestinal irrigations may pass the valve of Bauhin and reach the upper part of the small intestines. The advantages arising from rectal injections are the use of large doses, direct action, and the avoidance of gastric irritation. There are also other advantages attending this method. The use of cold water reduces the temperature; whereas hot water is of benefit in cholera. Thorough lavage of the intestines is also attained and a certain quantity of bacteria and ptomaïnes are mechanically removed. Cantani considers carbolic acid and tannic acid to be the best intestinal antiseptics. Corrosive sublimate exerts no antiseptic action, owing to its union with albumin. Tannic acid fulfils a double indication for rational intestinal antisepsis: it paralyzes the vegetative activity of the bacteria and renders the ptomaïnes innocuous. The value of tannic acid in effecting the objects already mentioned has received abundant clinical proof in the treatment of intestinal catarrh accompanied with fermentation and true specific dysentery. If the injections of tannic acid prove too irritating, then the addition to the injection of about one litre of oil is of advantage. In typhoid fever these injections are of great value; meteorism and diarrhœa disappear, and the entire course of the disease is favorably influenced. In the incipiency of this disease, it is possible by injections of tannic acid to abort it. Cantani has also secured an abortive action in the beginning of typhoid with injections containing one gramme of the hydrochlorate of quinine, and from ten to fifty grammes of pure carbolic acid in two litres of cold water.—*Wiener medizinische Presse.*

Treatment of Heart Disease in Pregnancy and Labor.—In an article on this subject, Dr. Mackness makes the following suggestions: Cardiac tonics should be avoided as long as possible, and never be used until there are evident signs of failure of compensation; before this appears careful diet, moderate exercise, and the use of iron and arsenic are all that are required. As soon as compensation threatens to fail, cardiac tonics act well, as a rule (except in certain cases of mitral stenosis, where they often have no effect); the best of them is, perhaps, strophanthus in small doses (*e.g.*, ℥iiss. of the tincture every four hours). It must be remembered, however, that prolonged use of these drugs after compensation has been restored tends to do serious harm, since the hypertrophy of the heart which they produce is followed by degeneration of its muscular fibres. The dose may be increased if necessary, and then gradually diminished again until eventually it may, perhaps, be discontinued altogether for a time. Strophanthus is especially useful where there is continued vomiting due to gastric congestion, and its own tendency to produce sickness may be counteracted by giving it with tr. cardamom co. If the venous congestion become very marked during pregnancy or labor, bleeding may, in some cases, give relief, at any rate for a sufficient time to enable the labor to be completed, and so allow the heart to again regain its power. Nitrite of amyl might, perhaps, be of use here, just as it was found useful by Dr. Fraser Wright during the third stage of labor. Since the bearing-down pains tend to increase the venous engorgement, chloroform should be given as soon as ever they appear, and the second stage of labor should be reduced to the shortest possible time; the administration of chloroform should be continued until after the placenta has been delivered. When Dr. Wright recorded the case where he used nitrite of amyl in the syncope which followed the delivery of the placenta, some difficulty was found in understanding how it could relieve the engorgement of the heart. The following explanation seems to the author, however, to be a reasonable one: The sudden delivery of the placenta causes an extra amount of blood to be thrown into the right side of the heart, since the abdominal veins are already over-distended; nitrite of amyl dilates the arterioles and lowers the blood-pressure, so that more blood would tend to pass into the systemic veins and thus engorge the right side of the heart still further. The veins, however, are already over-distended, so that no more blood can enter them, and hence no harm can be done thus by the drug; but at the same time the nitrite of amyl dilates the *pulmonary* arterioles as well as those of the systemic circulation, and hence the flow of blood through the pulmonary vessels is made easier, and the right side of the heart can empty itself and get relief. Hence we see that the important action of the nitrite of amyl in these cases is upon the pulmonary, and not upon the systemic arterioles.—*Edinburgh Medical Journal*, August, 1890.

Is Cancer Contagious, too?—The fact that certain spots constitute apparent foci for the spread of cancerous disease has ere now been noted, though we are still completely in the dark as to the causes which underlie these vagaries of distribution. It is, however, only by systematic close observation that we can hope to solve the enigma and acquire the knowledge which alone will enable us to check the ravages of a terrible and implacable disease. Some observations made by Dr. Arnaudet in the little village of Saint Sylvestre-de-Cormeilles, in Normandy, are interesting in this respect. The village only numbers some four hundred inhabitants, but among them the deaths from cancer are four times more numerous than at Paris (14.88 as compared with 4.16 per hundred deaths). In the course of his inquiry into the causes of this special mortality, Dr. Arnaudet discovered that there were certain "cancer nests" which the theory of contagion could alone explain. The water supply of these people is drawn almost exclusively from surface ponds, but he observes that very little water is drunk, though it is used in the manufacture of cider. He shows on a chart that the malady developed itself successively along a line corresponding to the water supply supplying the ponds, and he is evidently strongly inclined to attribute the outbreak to the water, or, secondarily, to the cider. He subsequently extended his observations to four neighbouring communes, in all of which the proportion of deaths from cancer was largely in excess of the normal rate. This inequality of distribution seems to point to the existence of local causative conditions, the nature of which it is highly important to elucidate.—*Medical Press.*

The Influence of Drugs on Intestinal Absorption.—Some important observations have been made at Jena on this subject. Dogs and cats were the animals experimented on. Iodide of potassium and grape-sugar were drugs the absorption of which was tested, while the drugs given with a view of ascertaining their influence on the absorption of the preceding were quinine, opium, morphia, alcohol, glycerine, common salt, and Carlsbad Mühlbrunnen water. The experiments showed that quinine, opium, and morphia, even in great dilution, diminished the absorption. Morphia had the same effect even when it was not applied directly to the mucous membrane, but injected interstitially into the tissues. Alcohol increased absorption in concentration of from 0.5 per cent. to 2 per cent., in a more concentrated form it diminished absorption more and more. Glycerine was indifferent, chloride of sodium one-fourth per cent. increased the absorption, while Carlsbad water had no effect one way or the other. When iodide of potassium was given to people in aqueous, alcoholic, or glycerine solution, and drunk in milk or Carlsbad water, when moderate addition of alcohol was made the quantity passed in the urine within a given time was increased. Glycerine had the same effect as water, Carlsbad water increased the quantity excreted; milk, on the contrary, diminished it.—Berlin correspondent *Medical Press.*

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & CO., Nos. 56 and 58 Lafayette Place

New York, September 27, 1890.

"WHAT IS THE PRESENT MEDICO-LEGAL STATUS OF THE ABDOMINAL SURGEON?"

THIS exceedingly pertinent question forms the subject of an admirable paper, read by Dr. W. W. Potter at the recent meeting of the American Medical Association. To some of our enthusiastic operators it will doubtless suggest ideas which are as disagreeable as they are novel, since they have hitherto cherished the belief that the laparotomist was a law unto himself. Accustomed to look upon abdominal section as an every-day procedure, attended with slight danger, they are inclined to assume, especially in hospital practice, that the patient and her friends should regard it with equal indifference. If the patient consents to the laparotomy no more formalities are thought necessary than in the case of a minor operation. The risks are touched upon lightly, if at all, and no doubt is expressed to her as to the inevitable cure.

To the scarred veteran of a hundred battles, as well as to the young soldier who has as yet only skirmished with the abdominal contents, we commend the warning contained in the paper under consideration. The author discusses at length the various medico-legal points which might be raised in court with regard to the skill of the operator, the conduct of the operation, and the after-treatment, and touches upon the question in which so much stress was laid in the famous case of the People of Kings County *vs.* Dr. Mary A. Dixon Jones, viz., whether a patient can insist upon being removed from a hospital at any time after she has submitted to abdominal section. He decides that "if sane she has the right to be removed at any time she may elect."

"She can go counter to, or in accord with, his advice as she may will."

But the questions which the writer emphasizes as of especial importance are these: Has the propriety of the operation been established "beyond reasonable doubt," and have the risks been clearly set forth to the patient and her legal guardians? Has her consent, and that of her friends, been obtained in a legal and binding manner? We fear that there are few laparotomists who would not be considerably embarrassed when asked if they always complied with these formalities before operation.

If the secret history of hospitals in New York alone were known, we would be astounded at the many narrow escapes which every institution has had from suits for malpractice, due not to want of skill on the part of the attending surgeons, but to their reckless disregard of ethical questions which assume such importance in private practice. A man who habitually underrates these is in constant danger. His brilliant reputation, his long series of successful operations will weigh lightly in the minds of a jury in comparison with a single unfortunate case. Like Banquo's ghost, the spectres of long-buried ovaries may rise "to push us from our seats." To the younger laparotomists this matter furnishes food for reflection. They might with propriety ask themselves, Is it safe to go on adding case to case with blind confidence in Fortune? Is it nice to exalt the operation above the patient? Does it pay to imperil reputation for the sake of adding to statistics?

A prominent specialist in a neighboring city was sued by a patient whose written consent to laparotomy he had obtained. He was vindicated only after he had been put to great expense and infinite annoyance, and after the case had been twice appealed. In the case of Dr. Jones every possible precaution had been taken. We venture to say that few surgeons in this, or any other country, would have been found so invulnerable beneath the fire of the prosecution.

No man who followed that memorable trial could fail to be reminded of the verse of Scripture, "If the righteous scarcely be saved, where shall the ungodly and the sinner appear?"

The remedy against legal persecution, to which every surgeon is liable, no matter how exalted may be his position, is a simple one. Unless the case is so urgent that delay is positively dangerous, no operation should be "rushed through" a day or two after a patient enters the hospital. The object of the operation, its risks, and the possibility that it may not be ultimately successful, should be frankly stated to the patient and to her friends by the operator himself, and not by the house-surgeon alone, as is sometimes done. It should be distinctly understood whether she elects to have both ovaries removed, if in the judgment of the operator this may seem necessary, or desires that one may be spared. Doubtless the safest plan is to obtain the consent of the patient and her guardians in writing; it should at least be given in the presence of several witnesses. The confident laparotomist frequently dispenses with all opinions save his own, regarding a consultation as a useless formality—an omission which might be seriously compromising in the court-room.

We have assumed that no flaw could be found in the operation or in the after-treatment, though these must be perfect indeed in order to bear the merciless criticism not alone of the laity, but of unfriendly medical witnesses. Remembering how rigid are the demands of modern abdominal surgery, the operator might well dread being called to account for an unsuccessful case in which he was conscious of having relaxed his usual vigilance. But what shall we say of the occasional operator, the recent graduate, who aspires to "do his first case?"

It may prove to be an expensive one if undertaken rashly, and without due consideration. He may be the unfortunate selected as the scape-goat to bear the sins of his more guilty elders. It is said to afford a certain satisfaction to a soldier under fire to reflect that a comparatively small proportion of the combatants are hit; but

the painful uncertainty as to his chances of joining the minority must prevent him from appreciating all the beauties of this theory. It is the same in our profession; no man knows when he will be the next victim. It behooves us to consider more carefully the rights of our humblest patients, and so doing to guard our own.

HOW TO INCREASE THE POPULATION IN FRANCE.

The Paris Academy of Medicine has been lately listening to some learned and lengthy communications made by Dr. Lagneau on the insignificant increase in the population of France. The author has suggested a number of measures to counteract this evil tendency in the life of modern France (*Bulletin de l'Académie de Médecine*).

1. To restrict celibacy and illegitimacy he advises that the numerous and onerous formalities exacted by the present marriage law should be greatly simplified, especially where the contracting parties are of different nationalities.

The limit of protection to the young girl should be extended from sixteen to twenty-one years of age, that is to say, to her majority. The seducer should be compelled to support his illegitimate child for a certain number of years, as provided by the laws of nearly all the European and American governments.

A special tax ought to be levied on bachelors over twenty-five or thirty years of age, the money so raised to go to the support of illegitimate children of unknown paternity. This suggestion is evidently based on the assumption that married men are all virtuous, and if carried out would doubtless lead to the establishment of Bachelors' Mutual Protective Associations.

The maternity hospitals should keep the young women much longer after confinement than they do at present, in order to prevent uterine affections, a frequent cause of subsequent sterility.

A better surveillance should be exercised over contagious diseases, and especially syphilis, so often the cause of infecundity and stillbirth.

The time spent in the army should be materially shortened by teaching the boys in the schools the art of war from the age of sixteen to seventeen.

2. To restrict sickness, mortality, and stillbirth he suggests that mothers' meetings or workrooms ought to be established, where the girl-mother, deprived of employment on account of her condition, can earn enough for the support of her child. If the mother is indigent, means should be given to her to enable her to nurse it, and not oblige her to hand it over to the administration.

He further urges that it is necessary to enforce the law in regard to adequate protection of infants.

To insure the carrying out of general sanitary measures, especially in the thickly populated districts, where tuberculosis and typhoid fever are rampant.

That rural camps for soldiers take the place of filthy city establishments.

To enlist for the colonies the indigenous population, and not the natives of France, who so readily succumb to yellow fever, cholera, typhoid fever, etc.

To counteract the steady drift of population from country to city.

The development of colonies is also advised, and with it the multiplication of commercial relations, which would tend to increase natality and reduce emigration.

The strangers and foreigners permanently residing in France should be naturalized as promptly and as completely as possible, so that they would share the expenses of the country with the others.

While some of these measures are sensible and seem quite practicable, others savor strongly of Utopia. The latter class will hardly appeal to the intelligence of French legislators, who will doubtless be called upon to take action by the committee appointed by the Academy to examine anew this whole subject. It certainly must be of the utmost importance to contemporaneous France to prevent a further falling away of her population. A power that means to retain its place in modern Europe needs able-bodied citizens, both of the military and civilian order. As Bismarck once put it, in the European fish-pond of to-day there are so many hungry pikes that it will not answer to be a merely edible carp.

LESSONS IN ANTHROPOMETRY.

The *Provincial Medical Journal* has lately given some attention and considerable space to the discussion of a letter with which it was favored, as to the "best way" of making young people tall. The inquirer is snubbed in the beginning of the discussion by being reminded that there is a passage in the Scriptures in which we are informed that a man cannot by taking thought add a cubit to his stature.

We are then informed that "in spite of all the labors of Quetelet, De Quatrefages, Edmund Parkes, and fifty other authorities on anthropometrical science, very little is known as to the causes which make some men tall and others short. Climate is asserted to play an important part. This is very doubtful, for some of the tallest races inhabit very hot climates. The hill country of India produces huge men. Many of the African tribes are of colossal proportions, and the South Sea Islanders are conspicuous for their immense stature. The Japanese are shorter than the Chinese, the Chinese than the French, the French than the English, the English are smaller than the people of the United States, and the latter conspicuously inferior to the Tonga Islanders. Race is a very important factor, though the influence of race is very irregular in its operation, and may show itself in the absence of short men, or in a high average stature; and in one case known to us a lofty average stature is accompanied by an almost entire absence of tall men. Everyone must have noticed the high stature of the English upper classes, who are several inches taller than their poorer brethren. A glance at any regiment will enable most of the officers to be spotted at once, and any large gathering of the clergy is conspicuously taller than one of non-conformist ministers. Town residents average an inch less than the rural population, thus showing the part which bad air and insufficient exercise play. It is known with absolute certainty that lads sent to work at an early age in factories and shops, or, for that matter, even in the open air, have their growth affected, the cause of this being that the immature frame cannot resist the double strain of growth and work. A sufficiency of good food is

admitted to be an important factor in developing growth, and all outdoor muscular exercises are good, provided that the system is not overtaxed by hard work and long confinement."

The average heights of the men of various nations are quoted from the tables of M. de Quatrefages, giving the standard of the Bosjesmans as 4 feet 6 inches; Mincopees, 4 feet 8½ inches; Lapps, 5 feet; Cochin Chinese, 5 feet 2 inches; Peruvians, 5 feet 3 inches; Malays, 5 feet 3 inches; Native Australians, 5 feet 3½ inches; Cingalese, 5 feet 4 inches; the Southern French and the Chinese, 5 feet 4 inches; the French working classes generally, 5 feet 5½ inches; the Northern French and the Arabs, 5 feet 5½ inches; the Russians and the Austrians, 5 feet 6 inches; the Germans and the upper French classes, 5 feet 6½ inches, which is also, according to him, the average of the people of Madras, the Belgians, and the English; the Roumanians and the Kabyles, 5 feet 7 inches; and, though surely this must be a mistake, the Sepoys of Bengal reach 5 feet 8½ inches.

To come to what may be looked upon as tall races, the Polynesian and the Pitcairn Islanders are stated to average 5 feet 10 inches; the Ojibbeways, the Agaces of the Pampas, the Kaffirs, and the Marquesas Islanders reach 5 feet 11 inches; the New Zealanders touch 6 feet, while the Patagonians range from a minimum of 5 feet 10 inches to a maximum of 6 feet 4 inches. The highest place of all on the list is given to the Schiffer and the Tongatabuan Islanders, who have an average of 6 feet 4 inches.

Now these are interesting particulars, but it seems to us that the *Provincial Medical Journal* fails to suggest an answer to the question put by its correspondent. We are persuaded, too, that the inquirer is rather unceremoniously silenced by the scriptural quotation. Evidently the man wanted to add a cubit, more or less, to his son's stature, not his own; therefore he can hardly be declared to be forbidden by holy writ to exercise the faculties that he wants to. Moreover, the question is simply asked, "Which of you, by taking thought," etc.; and nowhere do we find it stated, "Thou shalt not take thought," or words to that effect. The reply that "race is a very important factor" is interesting, as well as concise, but it is a hopelessly disappointing answer to the question of the anxious father of a short son; for we are very certain that neither by taking thought nor by administering medicine can a fond father change the race of his son. If the son is already there, no answer in the world could be more discouraging. But in the very measure of the improbability that a man can lengthen either himself or his son to any considerable degree, it *is* probable that he can produce some little effect upon his great-grandson.

The solution to the original question may be found in certain observations, particularly among the negroes of the West Indies. It is well known that the climates of these islands are quite similar; but the soil and vegetation differ in very marked degree. Now, the pure negroes, who are descended through lines of several generations that have lived in the West Indies, differ greatly in feature, shape, and temperament from their prototypes in Africa. Again, it is observed that they differ particularly in size and shape from each other, in accordance with the nature of the soil of the islands from which they happen to hail. Those, for example, whose native soil is particularly calcareous, are tall, raw-boned, sturdy fellows, able to withstand great hardships. On the other hand, the natives of soils that are poor in calcium, show it in their bones, at least after a couple of generations. Their limbs are more gently modelled; they are more graceful of stature, less hardy, and of lower average height. It is hardly probable that much calcium would make a short boy tall; and we are quite sure that it would be worse than useless for a man whose ambition lay in the direction of tall sons to feed them on calcium. At the same time it is evident that the soil, and the food that is indigenous to it, are important factors in determining to what height the sons of man shall rise. And it is well to preach to over-anxious parents a little of the gospel of humble acquiescence in the decrees of a "divinity that shapes our ends."

THE RADICAL CURE OF HERNIA.

It is a matter for regret that the name of him who first invented the truss is yet unknown, for he would deserve a place upon the highest pinnacle of fame. No single instrument or invention has perhaps added more to the sum of human comfort or increased so much the physical usefulness of man. We pay due honor to Paré and Lister, to Harvey, Jenner, Läennec, Morton, McDowell, and others of the immortals; but the man who invented the truss lies unknown and forgotten. It is, to be sure, just possible that the truss never was invented but "just growed," like Topsy, and this thought may afford some satisfaction to those who feel that they ought duly to honor those who have given great help to suffering humanity.

The history of the attempts to cure hernia reads much like that of the attempts to square the circle, find the philosopher's stone, or heal up the pus-soaked cavities of old tuberculous lungs. Not but that some progress has been made. The ancient methods associated with the names of Bonnet, Jobert, Belmas, Pirogoff, Wutzer, Wood, and others, are at least abandoned, and surgeons have stopped trying to fight the enemy in the dark. The open, direct methods associated with the names of Gross, Socin, Czerny, Macewen, and many distinguished American operators, are now admitted to be the only proper ones to pursue.

These methods are attended with a low mortality-rate, and apparently with cure in perhaps more than half the cases. In mild degrees of hernia the injection method has apparently also given good results.

A recent paper by Dr. William T. Bull (*Medical News*, July 5, 1889) shows, however, that a certain and safe cure for hernia has not yet been found, and that a more thorough study of the subsequent history of reported "cures" would show a larger percentage of relapses than has been supposed.

Dr. Bull reports the results of operation upon one hundred and thirty-four cases. These he divides into four series.

Series one, operated upon by the method of ligature and excision of sac, consisted of forty cases, twenty-two of which have been traced. Among the twenty-two were eight relapses.

Series two, operated upon by "the method of ligature,

excision, and suture" of the ring, consisted of thirty-nine cases, twenty of which have been traced. Among the twenty were eight relapses.

Series three, operated upon by "the method of ligature, excision, and suture of the canal," consisted of thirty-nine cases, twenty of which have been traced. Among the twenty were eleven relapses. The fourth series consisted of sixteen cases, occurring in children, with five relapses within a year.

With regard to the "newer operations" the writer has this to say:

"Each one has its earnest advocate; with a large number of theoretical advantages, or any brief period of observation, I doubt if any, subjected to the same continued scrutiny that my methods have been, will show better results. I am becoming confirmed in that judgment day by day, in witnessing the relapsed cases that apply for trusses to the Hospital for Ruptured and Crippled. Between January and October, 1889, there were forty-five such cases, and in the past nine months there have been fully as many more. Of the forty-five patients above mentioned, twenty-two have been further investigated. Of these, eleven had been operated on by McBurney's method, the shortest period of relapse being one month, the longest eleven months. Two had been subjected to treatment by injection, according to Heaton, with relapse at two months and eighteen months. In four operated on by ligatnre and excision, recurrence occurred on the average at the end of one year. One, by Macewen's method, recurred in seven months. One relapse took place four years after ligation and excision of the sac with suture of the external ring. Another five years after treatment by purse-string suture and inversion of the sac."

From the above we can infer rightly that the radical operation for hernia is not a thing to be indiscriminately applied. Its dangers have been much lessened, its results made more satisfactory, but the great majority of cases of hernia must, after all, trnst to the man who invented the truss.

News of the Week.

The Health Board and the Medical Record Right Notwithstanding.—The following letter is one of many we have received of late referring to the health statistics published weekly in the MEDICAL RECORD and is presented to our readers for the purpose of answering the criticism that it contains. The reports are officially furnished us by the Health Board, and are so printed without question, and we are pleased to note that the apparent discrepancies in the returns are so satisfactorily explained:

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Under head of "Medical Items; Weekly Statement" in the RECORD you made more deaths than cases in seven instances in the August numbers. Almost every table has an error of this kind. This looks bad for the leading medical journal of America. Look your files for past years over and prove what I say. More than half your tables are incorrect. Very truly,

A. C. FOLLETT.

HURON, S. D., September 12, 1890.

This was duly forwarded to the Health Department for an explanation and the following was promptly sent to us:

HEALTH DEPARTMENT,
DIVISION OF CONTAGIOUS DISEASES,
NEW YORK, September 24, 1890.

TO THE EDITOR OF THE MEDICAL RECORD.

DEAR SIR: Dr. Bryant has handed me the criticism made by one of your subscribers on the weekly report of contagious diseases published in your columns and furnished you by the Health Department.

The criticism states, "You made more deaths than cases in seven instances in the August numbers," and that "almost every table has an error of this kind." The matter is easily explained. The number of cases *reported* to the Health Department during the week ending each Saturday is given in a column entitled "Cases," and the number of deaths *occurring* during the same period in a column entitled "Deaths."

Among the contagious diseases will be found pertussis. The Board of Health does not enforce the reporting of this disease, consequently very few cases of it are reported, *but all the deaths from it are entered in the Bureau of Vital Statistics.* This is mainly the cause of the discrepancy. Whooping-cough has been very prevalent this summer and many deaths from this disease have occurred. Your correspondent writes as though he thought the "deaths" occurred among "cases" in the parallel column of the same table. This, of course, is erroneous. The deaths are distributed among all the existing cases. Those "cases" that have been sick for two, three, or even more weeks may die, and a number of deaths may occur at a time when there are but few new cases. Take for example a case in point. John Smith is reported as having cerebro-spinal meningitis during the week ending September 13th, and during the week ending September 20th no cases are reported but during the latter week John Smith dies. Here we have an apparent discrepancy, no cases and one death.

Your readers may have been puzzled at occasionally reading deaths from small-pox and typhus fever when no cases had been reported for many weeks. These were quarantine cases that were intercepted by the health officer of the port and sent to North Brother Island. Formerly they were not reported to the Division for Contagious Diseases, but deaths among them were certified to the Bureau of Vital Statistics. This is now changed, all cases from quarantine are reported as soon as they are landed on North Brother Island.

Yours respectfully,

CYRUS EDSON, M.D.,
Chief Inspector.

Alcohol and Tea.—Dr. Kraepolin, as the result of experiments upon the psychical effects of alcohol and tea, finds that the former substance in moderate doses hastens volitional acts, but does not hasten deliberative and associative processes. The purely reasoning processes, in fact, are lessened by alcohol. Tea, on the other hand, does not hasten volitional acts but does accelerate purely intellectual processes of association and reasoning.

Potassium Tellurate is the latest remedy said to be useful in the night-sweats of phthisis.

To Abort a Paroxysm of Whooping-cough.—Dr. Nägeli says that an attack of coughing in pertussis can be cut short by drawing the lower jaw downward and forward. Parents can readily be taught to make the simple manœuvre, which the author claims is always effective. The regular suppression of the paroxysms affects favorably, he says, the course and duration of the disease, and also prevents many of the complications caused by the violent efforts. The same procedure has been found effectual in restraining spasmodic coughing fits proceeding from other causes.—*Revue des Sciences Médicales.*

Acquired Color-blindness.—Dr. Thompson, writing in the *Journal of Railway Surgeons,* says that acquired color-blindness is often the result of the abuse of alcohol and tobacco.

Soft-handed Sons of Toil is what Dr. Oliver Wendell Holmes calls the members of the medical profession.

A Death from Hydrophobia is reported to have occurred on September 8, 1890, at Philadelphia.

The State Commission on Lunacy.—At a meeting of the New York State Commission on Lunacy, September 3d, the State was divided into insane-asylum districts, in accordance with the provisions of the State Care of Insane act, passed at the last session of the Legislature. The districts proposed are as follows, each comprising from six to ten counties: Utica District, Hudson River District, Middletown District, Willard District, Binghamton District, St. Lawrence District, and Buffalo District. Until such time as the State assumes full charge of the insane, the various counties will be required to pay for their own insane at the rate of $4.25 per week for all patients kept in hospital for three years or less, and $2.50 per week for those maintained for any period exceeding three years. It has been the practice in most State Asylums to take private patients who, by paying considerable sums, received special attention, private rooms, etc. The money obtained from these patients is used to promote the general comfort of the poorer class. The present State Commission have, we are informed, decided to abolish this system and to compel all patients to be treated alike.

The Railway Brotherhood Hospital Association was chartered at Springfield recently. Its object is to establish ultimately hospitals for the sole benefit of railroad men at convenient points between New York and San Francisco. It is expected that all the railroad brotherhoods will eventually come in and give the scheme their financial and moral support. A hospital in this city has already been secured.—*Medical News.*

Chicago has one thousand six hundred and twenty-one physicians, including all schools.

The Chicago Academy of Medicine is the name of a new medical society recently organized and incorporated.

A Chinese Medicine Company.—A curious fraud has been detected in Milwaukee, where a warrant was issued authorizing the arrest of Joseph A. Wilt, Dr. C. A. Jansen, and Jim Lee, alias Gun Wa, on a complaint sworn out by a city detective, charging them with conspiracy to defraud, obtaining money under false pretenses, unlawful assumption of the title of "doctor," violation of the pharmacy statute, and circulation of obscene literature. Gun Wa is an alleged Chinese physician and graduate of several Chinese medical colleges, who professes to cure all diseases known to man. Wilt is his manager and Dr. Jansen interpreter. Their office was established in July last and has done an enormous business. Wilt acted as manager and interpreter until March last, when the increase of business was such that it was found necessary to procure help and Dr. Jansen was brought on from Chicago to act as interpreter. An investigation was set afoot and it was found that the alleged doctor was a Chinese laundryman sent on from Denver by Frank L. Smith, head of the Gun Wa company, which has branches in Denver, Kansas City, Detroit, Indianapolis, and Milwaukee, and that neither Wilt nor Jansen, who acted as interpreters, could speak a word of Chinese. Since opening the office here a year ago three Chinamen have played the part of Gun Wa.—*Boston Medical and Surgical Journal.*

A Case of Self Mutilation.—Dr. E. M. Sutton reports the following case in the *Medical Age* of June 25, 1890. On May 30, 1890, a young married man, twenty-nine years of age, and the father of two children, secured a razor at midnight and deliberately ablated testes and penis. The only surgical aid given was to arrest hemorrhage, and an iodoform dressing. The wound has been dressed daily, and, although in healthy condition, seems to have made but little progress. The stump of penis is about an inch long, the skin retracted from it; the cut surface represents a typical cross-section, and exhibits but slow intent to heal, probably on account of the peculiar blood-supply of the corpora cavernosa and corpus spongiosum. It has been suggested to shave the pubes, freshen and unite the edges of the skin over the stump, and to leave a catheter in the urethra until healing takes place. The patient is of nervous temperament, and the unfortunate husband of a woman endowed with a gluttonish venereal appetite. He finally broke down completely. His wife twitted him as to his inability to satisfy her, and left him, emaciated and haggard, for stronger men. This preyed upon his mind till he obeyed the insane impulse to rid himself of the original cause of his condition.

The Third Italian Congress of Internal Medicine will be held in Rome on October 20th, 21st, 22d, and 23d. The Committee, presided over by Dr. Baccelli, and composed of Professors Cantani, Murri, Maragliano, and Rossoni, have decided that the following shall be the topics of special discussion: 1. The Etiology and Treatment of Pleurisy. 2. The Pathology of the Blood. 3. The Varieties of Polyneuritis.

Post-graduate Instruction at Johns Hopkins University.—It is announced that courses of instruction in medicine, surgery, pathology, and gynecology will be given by members of the medical faculty of Johns Hopkins University during the coming year.

Another Leper Colony.—A comparison of statistics regarding lepers in India during the thirty years, 1851–81, shows that their number has been increasing at the rate of about thirty thousand every ten years. During the last ten years the rate of increase is supposed to have been higher. It is rumored that steps will be taken to found a leper colony in one of the uninhabited islands in the Indian Ocean.

An Imperial Iridectomy.—The chief consort of the Shah of Persia has been residing at Vienna for some time past in order to undergo treatment for primary glaucoma, from which she has been suffering. The disease began four years ago in the right eye, and had run on to complete destruction, and the journey was undertaken in the hope of preserving the left eye from a similar fate. Iridectomy was performed by Professors Mauthner and Fuchs, and, so far, with every prospect of affording relief. The medical men are represented to have had a good deal of trouble in obtaining for their patient the necessary rest and quiet, in consequence of the affectionate officiousness of the *suite*, which consists of four ladies, three gentlemen, a physician, and, last, but not least, four eunuchs, all of whom are animated by a tender but embarrassing curiosity to know how things are going on, and are not to be deterred from invading the sick lady's chamber in quest of the latest information.—*Medical Press.*

Prevention of Conception.—The *Medical Press*, July 30, 1890, complains that in England the announcement of a marriage or a birth is followed by confidential letters offering, in exchange for the sum of one guinea, information bearing on the means of preventing any addition to the family circle.

What Are Ears for?—Ewald has made some experiments upon pigeons, which would seem to throw doubt upon the necessity of the ear as an organ of hearing. He removed the entire auditory apparatus, leaving only the end of the auditory nerve, and yet the animals experimented upon evidently had their hearing preserved in fair degree.

Why He Renounced Vegetarianism.—Dr. Alanus, the former leader of the vegetarians in Germany, has renounced his faith, and resumed the use of animal food. In a letter written to a local paper, he gives the reasons for his apostacy. He had lived for a long time, he said, on a purely vegetable diet without experiencing any ill effects, feeling no worse and no better than he had formerly while living as the rest of mankind. One day, however, he found that his arteries were apparently becoming atheromatous. He was unable to account for this, as he was not a drinking man, and was still under forty years of age. Finally he came across a statement by Monin, to the effect that abstinence from animal food was a fertile cause of atheroma. He could hardly have been much of a student of dietetics not to have come across that theory until his own arteries had become diseased. There is nothing like taking comfort out of everything, however, and he now consoles himself with the remark that he has "become richer by one experience, which has shown me that one single brutal fact can knock down the most beautiful theoretical building."

Sudden Death Following a Vaginal Injection.—Dr. Cheeves Bevill, of Winfield, Ark., reports the case of a woman, about twenty-five years of age, who was in the fifth month of pregnancy, and was suffering from prolapse of the uterus. A physician had ordered an injection of lead-water or alum, and this was given by the husband of the woman. After about two ounces of the wash had been thrown into the vagina the patient raised herself up, exclaiming, "I feel so funny," and sank back and died.

A Philanthropic Family.—Three brothers in Moscow Peter, Alexander, and Basil Bakhrushin, who not long ago built at their own expense a hospital for the treatment of chronic diseases, have just given the sum of 350,000 rubles (about $260,000) for the establishment of a home for incurables. Of this sum $75,000 will be employed in the construction of the building, while the balance is to be invested and the interest used to pay the running expenses of the home. The number of inmates provided for will be one hundred and fifty, and their ranks are to be recruited from former patients in the hospital for chronic diseases whom the physicians have pronounced incurable.

The Sale of Antipyrine.—Some idea may be obtained of the immense quantity of this drug which is consumed annually, when it is stated that the net receipts during 1889 of the firm which manufactures it amounted to 5,437,032 marks, or nearly $1,400,000.

Bacteria in Hail-stones.—Dr. Fontin has examined the water from melted hail-stones, and found it to contain a number of varieties of bacteria, among them being the already known bacillus mycoides, liquefaciens, luteus, sarcina lutex, and aurantiaca. Besides these, cultures of four other kinds were obtained, one of which was found by experiments on animals to be pathogenic. It is suggested that, since hail, snow, and rain are found to contain pathogenic bacteria, there may be a specific disease that can be the direct result of being wet through in a storm.

Late Pregnancy.—A writer in the *Medical World* reports the case of a woman, seventy-one years old, who gave birth to a healthy and well-developed boy.

Do Quakeresses Have Nasal Catarrh?—Dr. D. Hayes Agnew says that he never saw a case of nasal catarrh among the female members of the community of Friends, and he attributes their immunity to the protection afforded by their peculiar bonnets.

One More Glory for Chicago.—Since the opening of the Pasteur Institute in Chicago the residents of that progressive town are beginning to boast, with some reason perhaps, that the place is becoming a great hydrophobic centre. It remains now for St. Louis and Kansas City to get Pasteur Institutes, and see if they cannot also breed a few cases of lyssophobia.

Supposed to be a Maternal Impression.—Dr. Grace Danforth has reported a case in which a child was the exact image of a gentleman who sat opposite the mother at meal-time, and was not her husband. There was no question of paternity, the doctor thought, neither was there any reason to believe the woman harbored any feeling toward her vis-à-vis which she would not have been perfectly willing to acknowledge to her husband. The young man was red-headed and freckled.

Atropine as an Antidote to Cyanide of Potassium.—A case is reported in the *Deutsche Medicinal-Zeitung* of a man who swallowed with suicidal intent a quantity of cyanide of potassium together with a solution of atropine. He was taken to the hospital, but received no special treatment, and was perfectly well the following day.

Typhoid Fever in Richmond.—During the past summer typhoid fever has been very prevalent in and around Richmond, Va. The Academy of Medicine and Surgery of that city at its last meeting appointed a committee to investigate as far as possible the number of cases, the localities in which the disease prevails, and to propose such measures as may be beneficial to the public and the profession, in the way of preventing its further spread.

An Epidemic of Tetanus.—A number of the inhabitants of Friedburg, Silesia, have been attacked by a disease resembling tetanus, in which the muscles affected are chiefly those of respiration.

In Favor of the Decimal System.—The American Pharmaceutical Association, at its annual meeting held recently at Old Point Comfort, drafted a series of resolutions calling upon Congress to adopt the decimal system of weights and measures in all Governmental transactions, and for purposes of foreign and inter-State commerce, to take effect on the date of the landing of Christopher Columbus on this continent. The customary weights and measures used in the United States the preamble to the resolutions asserts to be arbitrary, unsystematic, inconvenient, and indefinite, governed partly by English law, partly by tradition, and partly by chance.

A New Cure for Rabies.—Somebody has lately put forward a new theory of hydrophobia, which has the merit of simplicity, at least, and opens the way to a most easy method of treatment. Under an attack of rabies, this genius asserts, the nasal artery becomes unnaturally distended, so much so that breathing becomes at times very difficult. The same artery, he says, passes down the back of the neck and swelling may be noticed at that point. His plan is, therefore, to stop the circulation in this artery at the base of the brain and lance the same artery where it passes through the nose. He allows as much blood to pass out as the patient's constitutional strength will allow, and then closes the aperture made by the incision. Thus does the art of healing make giant strides in these latter days.

Dr. Marcello Hutchinson, the First Assistant Physician at the State Lunatic Hospital at Taunton, has been chosen Superintendent of the Massachusetts Hospital for Dipsomaniacs and Inebriates.

Drawing the Color Line.—A little excitement was caused recently in the Training School for Nurses at the Philadelphia Hospital by the admission of a colored pupil from Oberlin, O. Some of the white pupils objected to her presence among them and drew up a protest against her admission, but were persuaded to withdraw their opposition, and now harmony once more reigns.

A New Hospital in Macon.—An effort is being made in Macon, Ga., to found a free hospital in that city. The "King's Daughters" have raised the sum of $1,500 as a nucleus, and this has aroused general interest in the undertaking. Subscription lists have been prepared, and the promoters of the object have little doubt of ultimate success.

The New York Pathological Society will hold its meetings in the future in the new building of the Academy of Medicine, No. 19 West Forty-third Street.

The Doctors are home again, and the Berlin Congress has passed into history.

Unhealthy Station Houses.—The Board of Health in Albany has had an inspection made of the police stations in that city, as a result of which many have been found to be in a decidedly unsanitary condition.

The Use and Abuse of Pepsin.—The following are the conclusions of a paper read by Dr. Gustavus Elliot at the last meeting of the Connecticut State Medical Society: 1. Patients suffering temporarily from the ingestion of an excessive amount of nitrogenized food may obtain relief by taking pepsin, but it is very much more important that they should be warned of the evil consequences which will result from the repetition of such overindulgence. 2. When annoying symptoms are the result of imperfect digestion of nitrogenized food, which has been taken in moderate amount, and when this is due to a deficiency in the quantity or quality of the gastric juice, it is more important to endeavor to increase the secretion of the gastric juice, than to try to supplement the deficiency by the administration of an artificial pepsin. 3. In acute or chronic indigestion, or dyspepsia, pepsin is sometimes of great value for the immediate and transient relief of distressing and debilitating symptoms, while other measures are being employed to restore the digestion to its normal activity. 4. During the course of, and during convalescence from, certain acute diseases, as well as in some chronic diseases, characterized by transient weakness of the digestion and defective assimilation, pepsin is of considerable value in assisting to increase the assimilation of food. 5. When used for the cure of chronic indigestion and dyspepsia, pepsin is a snare and a delusion, giving a transient feeling of comfort, without increasing the digestive power of the stomach.

Dr. Agnew Once a Shopkeeper.—It is related of Dr. D. Hayes Agnew, that many years ago, after he had worked in vain for two or three years to get enough medical practice to support him, he dropped physic in disgust and went to keeping store at Newton, Delaware County. There, in a small shop, he sold tarred rope, sickles, sunbonnets, molasses, and rakes, nails, and flour, and fish-nets. But his passion for surgery and medicine made storekeeping galling, he gave it up, risked starvation in a desperate battle with fortune again, and won.

No Doctor Needed.—A wayfarer lately, in a primitive part of Kent, inquired of a rustic whom he met whether there was a doctor near, as he had hurt his foot and wanted it looked to. "Doctor, sir?" said the man, with a knowing shake of his head. "There ain't no such thing about here. If we sprains ourselves, or has the toothache, we goes to the blacksmith; but, thank God, we all dies natural deaths."

"Archivos Internacionales de Laringología, Otología y Rinología," is the name of a bimonthly journal recently established under the editorial management of Dr. Ricardo Botey, of Barcelona, printed in Spanish though published in Paris, and is intended to be the organ of specialists in diseases of the upper respiratory passages in either Europe or America, whose mother-tongue is Castilian. The first few numbers of the journal present a very creditable appearance.

BRITISH MEDICAL ASSOCIATION.

Fifty-eighth Annual Meeting, held at Birmingham, England, July 29, 30, 31, and August 1, 1890.

(From our Special Correspondent.)

(Continued from page 334.)

SECTION IN OBSTETRICS.

FIRST DAY, WEDNESDAY, JULY 30TH.

Management of Tedious Labor.—DR. PLAYFAIR opened a discussion on "Modern Methods of Managing Lingering Labor." After alluding to the older methods which had fallen into disuse, as tartar emetic, bleeding, belladonna, etc., and mentioning the case of the Princess Charlotte as illustrating the great dread of the use of the forceps which prevailed at that time, the unfortunate princess lying with the head almost on the perineum for hours, when she could have been safely and easily delivered at any time with the forceps, he enumerated the modern methods. He considered chloral hydrate far superior to chloroform or opium in cases of rigid cervix, and strongly urged its use in doses of fifteen to twenty grains, repeated if necessary. He spoke strongly of the good effect of pressure on the uterus through the abdominal wall. He remarked that he had brought nothing forward striking or new, but wished to elicit the opinions of members on the modes now in use.

DR. WILLIAM WALKER advocated the use of opium, and spoke of its value in allowing the practitioner a night's rest.

DR. ROBERT BELL, of Glasgow, spoke of strychnine and gelseminum as being useful.

DR. MURDOCH CAMERON, of Glasgow, advised friction to the uterus in preference to pressure, and urged the importance of studying the position of the fœtal head. He mentioned a case in which tr. opii, ʒ j., given in mistake for ergot, accelerated labor, and produced rapid delivery.

DR. WILLIAM DONOVAN, of Birmingham, criticised the large dose, fifteen grains quinine, given by Dr. Playfair.

DR. AUST LAWRENCE, of Bristol, spoke of the value of hot-water injections in rigid cervix. Considered ergot in small doses useful to induce typical uterine contraction, especially where the uterus had been over-distended. He also mentioned that alterations in the position of the woman often accelerated second stage.

DR. CULLINGWORTH, of London, considered that the disposition to interfere in first stage decreased as men got older. Opium was in his opinion the best remedy in lingering first stage; given freely it diminishes suffering, and is of help, when the pains are useless, by diminishing irritability; he would urge the importance of distinguishing between high and low forceps operations; injury in high operations underestimated, lacerations of vagina often caused by slipping of blades from head, and these allowed absorption of septic matter. Mentioned that in Egypt, where forceps are never used, vesico-vaginal fistulæ are common and lacerations of perineum rare—the former being much more commonly caused by prolonged pressure of fœtal head than by forceps.

MR. C. J. WRIGHT, of Leeds, considered chloroform not advisable in first stage, but useful in second; mentioned use of cocaine made into pessaries with cacao butter, or of incision of the edge of perineum by two lateral cuts. Older writers advised waiting six hours after feeling head and ears before applying forceps. Mentioned that forceps were often useful as a "brake" power.

DR. LEITH NAPIER, of London, said there was a difference between surgical anæsthesia and that needed in labor. He advised the application of cocaine on pledgets of wool. He had found injections of hot water useful in cases of rigid cervix. In exceptional cases he advised incising the os. He suggested antipyrin in fifteen-grain doses as a substitute for chloroform, chloral, etc.

DR. SMILY, of Rotunda Hospital, Dublin, dwelt on the importance of limiting vaginal examination; he found vaginal examination always attended by rise of temperature. The principle at present in vogue at the Rotunda was one of non-interference.

DR. MORE MADDEN, of Dublin, advocated the use of ergot in management of second stage when delay was due to inertia, giving three to four drachms at one dose during this stage, and hypodermic injection of ergotine as well. He ridiculed the dangers ascribed to meddlesomeness in midwifery.

DR. BENINGTON, of Newcastle-on-Tyne, agreed with Dr. Playfair's praise of chloral.

DR. EDIS, of London, urged the importance of taking a broad view of the case, studying each case on its own merits and acting accordingly. He advised pressure on the uterus during a pain. He also spoke of the importance of putting the head in a favorable position in one oblique diameter.

DR. GORDON, of U. S. A., asked Dr. Playfair's opinion of the value to be attached to the action of the voluntary muscles in labor, *i.e.*, the advantage of the advice to "bear down."

DR. A. J. SMITH, of Dublin, drew a distinction between hastening and inducing labor. For rigidity of the cervix he used vaginal injections of hot water. In the second stage he considered the indications for interference to be: *Maternal*—quick pulse, vomiting, rise of temperature. *Fœtal*—passage of meconium, irregularity of fœtal heart.

DR. BYERS, of Belfast, also found that the temperature rose after frequent vaginal examinations. He urged importance of antiseptic precautions and of employing only trained nurses. He advocated warm baths in rigid cervix, etc. He would not use ergot before the birth of the child, except when post-partum hemorrhage was probable. He used chloroform in nervous women to allay excitability.

DR. HEYWOOD SMITH, of London, mentioned that Polish midwives smeared the cervix with belladonna to induce dilatation. He spoke of the value of the binder in hastening labor.

DR. CLARK, of Massachusetts, U. S. A., asked Dr. Playfair's opinion on comparative advantages of forceps and version in lingering labor.

DR. PLAYFAIR, in closing the discussion, said that he was pleased to find so much agreement with the views he had expressed.

In reference to the use of opium, he had often found that large doses had a good effect by their reviving power in severe cases of post-partum hemorrhage; he thought that the same dose might in one case produce quick delivery from its stimulating effect, and in another delay from its sedative action.

DR. BARBOUR, of Edinburgh, then read a paper on recent results from the study of labor, especially of the second stage, by means of frozen sections and casts.

The sections were beautifully prepared, and there were casts both of the genital tract and of the fœtus.

The principal point established by the researches was the distinct division of the genital tract, during labor, into two portions, viz., an upper, formed by the upper uterine zone; the lower, formed by the lower uterine zone, the cervix, and vagina, the line of demarcation being quite distinct at the internal contraction (Bandl's ring). The muscular tissue of the upper part alone had any propulsive power over the fœtus, so that when it had passed entirely into the lower portion propulsion was only secured by the action of the voluntary muscles.

DR. BERRY HART, of Edinburgh, congratulated Dr. Barbour on the great scientific interest of his paper, and the extreme alue of his contributions to obstetrical science. He suggested that reproductions of the sections should be distributed to medical schools for educational purposes.

DR. WALLACE, of Manchester, in alluding to the casts of the fœtus which presented by the breech, remarked that

the arm was immediately below the chin, and alluded to the importance of this in producing flexion.

Dr. Aymard, of Ipswich, then showed an axis pressure binder devised by himself for use in prolonged second stage.

Dr. Aveling, of London, read a paper entitled "Are Midwives to be Abolished or Bettered?" He gave statistics of the number of labors which it was calculated were attended by midwives, and advocated the "bettering" of midwives, and approved the amended bill bearing on the subject now before Parliament.

Dr. Rentoul, of Liverpool, read a paper entitled "On the Registration of Midwives and their Power to Practise Independently of the Profession," in which he strongly opposed the present bill on the ground that it did not sufficiently limit their duties, and would result in their doing work which should properly be done by the medical man.

Dr. Cameron thought that they should be registered.

Dr. Aust Lawrence, of Bristol, and Mr. Hallwright, of Birmingham, agreed with Dr. Aveling. Mr. Atkinson, of Leeds, agreed with Dr. Rentoul.

Second Day, Thursday, July 31st.

Gonorrhœa as a Cause of Pelvic Inflammation.—Dr. Granville Bantock opened a discussion on "The Importance of Gonorrhœa as a Cause of Inflammation of the Pelvic Organs." In his opening remarks he mentioned the views of Noeggerath, Neissler, and Sinclair on the matter, severely criticising them, and stating his opinion that they had considerably exaggerated the frequency with which evil results followed gonorrhœa in the female, and ridiculing the idea of the "old and decrepit gonococcus" being awakened into new life after a period of inactivity. He stated his own disagreement with the view of Dr. Sinclair, that gonorrhœa might affect the uterus and appendages without any micturition trouble having been noticed.

He did not believe that gonorrhœa was a frequent cause of sterility in women, and had never met with a case of inflammation of the pelvic organs unmistakably due to gonorrhœa.

In conclusion he summed up his views in the following words:

"My opinion, then—an opinion founded on my own observation—is that the importance of gonorrhœa consists in the fact that in a few or limited number of cases it seems to be capable of producing most serious symptoms—rarely, however, terminating in death—and that this importance is diminished by the fact that such cases are comparatively rare."

Dr. Morison, of Newcastle-on-Tyne, related the case of a man who married six months after an attack of gonorrhœa. Three weeks after marriage his wife had an acute attack of pelvic peritonitis, from which she recovered, but still had recurrent attacks. In his opinion pelvic peritonitis was a more common sequel than distinct disease of the tubes. He also related a case of fatal arachnitis, due to pyæmia, the result of gonorrhœa. He believed gonorrhœa was a much more serious complaint than Dr. Bantock imagined.

Dr. Braithwaite, of Leeds, considered that the spreading of gonorrhœa to uterus and tubes depended on the degree of patency of the cervical canal. He believed that the recurrent attacks of pelvic peritonitis were caused by periodical discharge of pus from the outer ends of the Fallopian tubes, and when the tubes were closed at the outer end similar discharges sometimes took place into the uterus.

Mr. Noble Smith, of London, in his experience as house surgeon at the Female Lock Hospital, had found no cases of peritonitis following gonorrhœa.

Dr. Inglis Parsons, of London, asked what Noeggerath's supporters meant by latent gonorrhœa? He had one or two undoubted cases of gonorrhœa having inflammation of vulva and urethra each week in his out-patient practice, but had seen no evil results follow.

Dr. Heywood Smith, of London, said he would like to know why the inflammation expended itself on the urethra and vulva rather than on the os uteri. He related the case of a mother of eight children who contracted undoubted gonorrhœa from her husband, which was followed by peritonitis.

Dr. Leith Napier, of London, considered Dr. Bantock had minimized the evil results of gonorrhœa. In his opinion, excluding parturition, gonorrhœa was one of the most frequent causes of inflammation of the tubes, etc. He related the case of a husband suffering from syphilis, who had not infected his wife, though having intercourse while he had a chancre, and from that argued that because one case did not do it, it was no proof that it could not be done, which was the line of argument pursued by some speakers in reference to the effect of gonorrhœa.

Dr. Wilson, of Baltimore, U. S. A., said he could not recall a single case in which tubular or ovarian inflammation had followed gonorrhœa. He related three cases of undoubted gonorrhœa not followed by any symptoms.

Dr. James Murphy, of Sunderland, thought Dr. Bantock had minimized its importance, and related a case in which pyosalpinx clearly followed gonorrhœa.

Dr. Gordon, of Portland, U. S. A., did not consider urethral trouble common in gonorrhœa in females. He drew attention to injuries (from operations on cervix, etc.) as a much more common cause of inflammation of the tubes and ovaries, and quoted Dr. Wylie, of New York, as a believer in the potency of gonorrhœa as a cause. He drew attention to cases of non-specific urethritis in man, and pointed out the difficulty in some cases of diagnosing the cause of that condition.

Dr. Cullingworth, of London, held opposite views to Dr. Bantock. He quoted the case of a young girl who had gonorrhœa, followed by ovaritis, first on one side and then on the other. Abdominal section was performed. On one side the outer portion of the Fallopian tube contained pus; toward its inner end was a cicatrix, through which pus had evidently burst into the peritoneum, setting up violent peritonitis, which was thought to be an attack of ovaritis. On the other side the outer end of the tube was expanded, forming a hydrosalpinx, and the inner formed a pyosalpinx, which was on the point of bursting into the peritoneum. He believed that Dr. Bantock would soon meet with cases which would convince him that his views were wrong; but quite agreed that the subject had been exaggerated. He attached no importance to the negative evidence which had been brought forward. He also pointed out the frequency with which a pyosalpinx formed without any pain having been felt.

Dr. Edis, of London, held an entirely contrary view to Dr. Bantock, and said he had met with numerous cases which clearly bore out the fact that a gonorrhœa caused these inflammations. He pointed out how often symptoms came on soon after marriage, no other cause being possible.

The President (Dr. Savage) said he sided with Drs. Cullingworth and Edis, as he saw many cases bearing out their opinions. He advocated the removal of the appendages as the only proper cure for those cases of pyosalpinx, etc.

Dr. Bantock, in reply, said that he had not attempted to minimize severity of result, but had admitted it on question of frequency. He considered gonorrhœa a serious disease, and would never look on it as otherwise. He agreed with Dr. Cullingworth as to the frequency of absence of pain in pyosalpinx. He did not think vaginitis a common symptom of gonorrhœa, the gonococcus was said to be unable to find a resting place in the vagina.

Dr. Auvard, of Paris, sent a communication which was read by the Secretary, on "An International Nomenclature of the Presentations of the Fœtus," which was illustrated by diagrams. He pointed out that the fœtus in

utero consisted of two ovoids, the "cephalic" or head, and the "cormic" or body (κορμος, trunk); each ovoid might present by its large extremity, small extremity, or intermediate part, and the presentations in this way corresponded thus: Presentation of large extremity, cephalic ovoid, occiput; cormic ovoid, breech. Presentation of small extremity, cephalic ovoid, chin; cormic ovoid, thorax, including shoulder presentation. Intermediate part, cephalic ovoid, forehead; cormic ovoid, back or abdomen. These presentations corresponded in point of frequency.

No discussion followed this paper.

Dr. Edis, of London, read a paper on "The Clinical Treatment of Sterility." After stating statistics he remarked that fashion had an important bearing on the treatment, at one time displacements being considered the cause which required treating, at another inflammation or stenosis. He enumerated most of the operations and other procedures which had been carried out, mentioning that catheterization of the Fallopian tubes had been advocated. He urged the importance of a thorough vaginal and bimanual examination, and of a correct diagnosis, before proceeding with any treatment, and remarked that in some cases all that was necessary to effect conception was a change of diet and habits, as sterility was common in the indolent, overfed, and fat. He preferred to examine bimanually, with the patient in bed and on the back. He urged the importance of excluding causes due to the husband. He had treated undeveloped uterus successfully by hot douches and electricity. He urged the necessity of taking a comprehensive view of the question.

Dr. Aust Lawrence, of Bristol, also found sterility in women who lived too well and took little exercise. Had treated cases of closed cervix very successfully by passing negative current by means of sound introduced into cervix.

Dr. More Madden considered ninety per cent. of the cases were due to stenosis of the cervix or of the Fallopian tube. He used the sound to straighten and dilate the cervix, and made a crucial incision of the os with Simpson's urethrotome, followed by forcible dilatation.

Dr. Wilson, of Baltimore, urged the importance of first being satisfied that the husband was not at fault. He regarded anteflexion as a common cause, and one which admitted of successful treatment. He believed the anteflexion was in most cases the result of habitual constipation at the time of puberty, the loaded bowel pressing on the fundus uteri at the time that organ began to grow and pushing it into anteflexion. He urged the importance of a daily evacuation of the bowels, especially at that time of life. He never used tents or forcible dilatation. In anteflextion and stenosis he split the posterior lip of the cervix with scissors and divided the anterior angle with urethrotome; cure followed in seventy-five per cent. of these cases.

Dr. Heywood Smith agreed as to constipation acting as a cause, but thought it acted by pushing the cervix upward and forward rather than on the fundus. He thought that a large division of os interfered with the grasping action which took place during coitus. He advised a small incision and dilatation by a stem.

Dr. Bell, of Glasgow, had had unfavorable results from incision, and did not attach much importance to stenosis. He advised curetting diseased endometrium and applying iodized phenol.

Mr. John W. Taylor, of Birmingham, urged the importance of distinguishing causes which were curable. In his experience sterility was sometimes caused by unilateral disease of the appendages, and after the removal of the diseased appendages conception had ensued.

Dr. Gordon, of Portland, U. S. A., considered the pathological condition of the endometrium the cause in most cases. He did not agree with Dr. Wilson on posterior section of cervix, but preferred gradual dilatation by means of a screw, washing out uterus with solution of perchloride of mercury by means of a double-current tube, and applied pure carbolic acid to interior.

Mr. John W. Taylor read a paper entitled "A Contribution to the Study of Acute Exanthematic Inflammatory Disease of the Uterine Appendages." He recorded a case of scarlet fever in which, twenty-eight days after the onset of the fever, symptoms of acute pelvic peritonitis appeared. He opened the abdomen and found a collection of pus in the peritoneum; the inflammation appeared to be due to the irritation caused by the discharge of the contents of a Graafian follicle, which had just ruptured in the left ovary.

Third Day, Friday, August 1st.

Abdominal Section vs. Craniotomy.—Dr. Murdoch Cameron, of Glasgow, opened a discussion on "The Relief of Labor, with Impaction, by Abdominal Section as a Substitute for the Performance of Craniotomy." He laid down that when the conjugate was below three inches the child could only be saved by Cæsarean section. He was in favor of Cæsarean section where the case was seen early, but opposed to operation before the onset of labor. He favored Porro's operation, where the uterus had been injured by prolonged attempts at delivery. He arrested hemorrhage by pressure of fingers on edges of wound, and used multiple sutures through outer two-thirds of uterine wall, taking in peritoneum. He then gave particulars of the three cases he had operated on.

The first case was that of a primipara, aged twenty. The conjugate was only one and one-half inch. The patient had been in labor sixteen hours; mother and child recovered. Second case, aged eighteen, rachitic; C. V. one inch; both tubes tied; child and mother recovered. Third case, aged twenty-three, primipara; C. V. two inches; child and mother recovered.

Diagrams and drawings were shown of the cases, and an interesting photographic group, depicting one of the cases, who married shortly after, attended by the other two patients as bridemaids.

Dr. Harris, of Philadelphia, sent a communication which was read by the Secretary. He advised suturing the uterus in two rows—deep and superficial—and evacuating uterus *in situ*. He did not advocate tubal ligation except in single women or married women who had borne two children. He would like to see craniotomy done under C. V. of two and one-half inches compared with best results of abdominal section.

Dr. William Walker asked for a definition of impacted labor.

Dr. Aust Lawrence noticed that Dr. Cameron did not put an elastic India rubber tube round the uterus for fear of asphyxiating the child, and dwelt on the importance of studying the condition of the child and pelvis thoroughly. He asked would Dr. Cameron advise operation before labor commenced?

Dr. More Madden held that destruction of child was never justifiable. He also protested against the proposal of Mr. Tait to do Porro in placenta prævia.

Dr. Willingworth said he had done three cases—one Porro, two Cæsarean; both Cæsarean died, the Porro recovered. He thought that more statistics as to results were required before preference could be decided. All his three cases had been in labor some time before operation. He was in favor of choosing his own time for operation and not waiting for labor to begin; if uterine inertia does come on when operation has been done before labor has set in, then we should go on and do a Porro. He did not think the elastic tube caused any danger to the child. He asked whether Dr. Cameron placed the sutures so as to avoid decidua? He urged importance of keeping the incision above retraction ring. He answered the question, "Is Porro's operation good for placenta prævia," emphatically "*No*," because in the first place there was already a satisfactory method of treatment, and bad results were due to ignorance of Dr. Braxton Hicks's

method of bipolar version. In the second place, if Porro's operation were done, the lower part of the uterus was in an unsatisfactory condition for forming a pedicle.

Dr. Heywood Smith, of London, said he preferred Porro's operation because it was more easily done and had the advantage of preventing subsequent pregnancy. He approved of making the incision at upper part of uterus, because that would render it more easy to proceed to Porro's operation afterward.

Dr. Granville Bantock considered craniotomy a disgrace to the profession and never advisable. It was always possible to obtain skilled assistance because of warning beforehand. He preferred Porro's operation as being more easy. He would vote for sterilization, and considered tying tubes more dangerous than removing appendages. He did not see the necessity of elastic ligature, and considered it dangerous to child. He gave his decided vote against doing Porro for placenta prævia, and considered that the mortality of cases treated otherwise did not warrant our doing so serious an operation.

Dr. Leith Napier, of London, thought that Dr. Bantock went too far in saying craniotomy was never needed; cases where conjugate measured two and a half inches would be treated better by general practitioners by craniotomy. He thought Tait's statement that the mortality of placenta prævia was thirty per cent. was monstrous.

Mr. William Donovan, of Erdington, said his experience was that in many cases the child was dead, and then craniotomy was the only thing to be done.

Dr. Beverley, of Norwich, narrated a case in which the conjugate diameter was two and a half inches. During labor a consultation was held. Porro's operation was advised and successfully performed.

Dr. Bell, of Glasgow, thought craniotomy should never be performed.

Mr. C. J. Wright, of Leeds, thought Porro's operation not justifiable in placenta prævia. There were always a certain number of cases where craniotomy was unavoidable. The use of the cephalotribe should always be combined with craniotomy. He asked whether Dr. Cameron removed a piece of uterine wall, so as to leave overlapping peritoneum. He advised removing the appendages.

Dr. St. Clair Gray, of Glasgow, had helped Dr. Cameron in his cases, and in his opinion the danger of hemorrhage had been exaggerated. He thought that in cases when at the next pregnancy a living child would be delivered prematurely craniotomy was preferable.

Dr. Smily, of Dublin, was of opinion that craniotomy should be done sometimes, *e.g.*, in hydrocephalus, in accidental hemorrhage when severe, and in cases which have been allowed to go on in labor. Abdominal section was always better where the conjugate was under two inches.

Dr. Walter thought craniotomy was advisable in some cases, especially in cancer of cervix. He had seen two cases of Porro; no elastic tube was used, but there was no hemorrhage.

Mr. Lawson Tait said that from an ethical point of view destruction of the infant was unjustifiable, and considered so by the Roman Catholic Church, which was the only body which had discussed the question. In his opinion the choice of operation was entirely a matter of statistics. He advocated sterilization, because where you have a choice of two methods of treatment, one of which cured and the other relieved, you should choose the one which cured. As to Porro's operation for placenta prævia his experience of the mortality of other methods of treatment led him to suggest "Porro." He thought there were no satisfactory statistics as to the mortality of the condition.

Dr. Cameron, in reply, said that he had experienced no difficulty in regard to hemorrhage in his cases; he had not used the elastic tube, and would prefer to use a bandage to using tube. He avoided the decidua in passing his sutures, and agreed with Dr. Cullingworth that incision should be carried up toward fundus, and should not encroach on lower uterine zone. He would sometimes do a craniotomy on the first child, and deliver subsequent ones prematurely.

Mr. Lawson Tait then read a paper on "A Record of 219 Cases of Operation for Removal of the Appendages for the Treatment of Uterine Myoma, performed between March 16, 1883, and December 18, 1888, giving the Subsequent History of the Cases from Twenty Months up to Seven Years' Subsequent to the Operation." In these 219 cases there were four deaths, giving a mortality of 1.82 per cent. The total number of cases to end of 1888 had been 327, with six deaths. He quoted several cases at haphazard from the list, and summarized his general conclusions as follows: Of the 215 cases (219 — 4) there were three failures. One patient became insane, but, on the other hand, three patients previously insane recovered their reason after the operation. The tumor seldom needed removal unless pressing on organs, and so causing symptoms. The tumors shrank much more after the operation in the young than in older women. His opinion was decidedly adverse to treatment by electricity.

Dr. Beverley, of Norwich, read a paper on "A Case of Ligature, but *not* Removal of the Appendages, for the Treatment of Excessive Hemorrhage from Uterine Myoma." In this case the intention had been to remove the appendages, but these were found so bound down by adhesions that this was impossible. The tubes were therefore ligatured, and a good recovery and cure resulted. He asked Mr. Tait's opinion on the proceeding.

Dr. Aust Lawrence, of Bristol, urged the importance of first trying medical treatment. Electricity had produced good in his hands, and he had met with no bad results. He had made six hundred applications; the results had been good, hemorrhage being arrested.

Dr. Bantock agreed with Mr. Tait that some cases were not benefited. He had found the tumor disappear gradually after operation, with no bad symptoms in eighteen months to two years. He had also found disappearance more rapid the younger the patient.

Dr. Byers, of Belfast, inquired what influence the size of the tumor had in deciding whether the operation should be oöphorectomy or hysterectomy?

Dr. Heywood Smith recorded a case of intermittent melancholia which seemed to be associated with menstruation; after removal of the ovaries there was no recurrence.

Mr. Lawson Tait, in reply, remarked that the advocates of electricity only used it in "suitable" cases, whereas his cases were quite unselected, being taken just as they came. He always opened the abdomen with the intention of removing the appendages, and then, if he found it necessary, proceeded to do hysterectomy. He had not tried oöphorectomy for insanity, but in epilepsy had done it sometimes with good results.

What's in a Glass of Beer.—A writer in a German newspaper has had the temerity to jot down the ingredients which go to make up a glass of beer in Germany. The pharmacopœia of the beer barrel this scientific man sets forth in alphabetical order. We give the German nomenclature for fear of spoiling the brew. It consists, says the writer, of alcohol, althopfenöl, aloe, belladonna, biercouleur, bilsenkraut, bitterklee, buchenspäne, caraghenmoos, coloquinten, enzian, fichtennadeln, gogel, gelatine, glycerine, haselnuszspäne, hausenblase, herbstzeitlose, hopfenaroma, hopfenbittersäure, Ignatiusbohne, ingwer, kamille, kartoffelzucker, kardobenedictenkraut, kokelskörner, koriander, lakritzensaft, laugensalz, malzextract, metallsalze, mohn, moussirpulver, natron, nieszwurz, nux vomica, pikrinsäure, pottasche, quassia, reis salicylsäure, schafgarbe, Spanischer pfeffer, soda, stärkezucker, stärkemehl, strychnin, syrup, tannin, tausendguldenkraut, tischlerleim, wachholder, waldmeister, weidenschalen, wermuth, zuckercoulör, etc. This is why we *pass* on lager.—*Pharmaceutical Record.*

Correspondence.

COMMENTS ON A CASE OF ACONITE POISONING.

To the Editor of the Medical Record.

Sir: On September 1st, Mrs. Catharine S——, of New York, died from taking an overdose of tincture of aconite. The drug had been prescribed by a reputable physician, for her grandchild, a baby. It was directed that six drops should be put into a glass of water and one teaspoonful given hourly. The grandmother, wishing to see if it would be disagreeable to the child, swallowed, as estimated, about two teaspoonfuls from the bottle containing about two and a half ounces. The mother also sampled it, taking much less. She then put six drops of it into the glass of water and gave to the baby as directed.

Both the doctor and the drug clerk, who put up the prescription, say that they gave special caution to be careful how the medicine was used, as it was dangerous.

In a short time after tasting the drug, both the grandmother and the mother were seized with the characteristic symptoms of aconite poisoning. Physicians were hurriedly called, but in spite of all they could do, Mrs. S—— died in about two hours. Her daughter's life was barely saved.

This case furnishes an excellent text for some practical observations. It will be asked—"Why should two and a half *ounces* of aconite be ordered, when the baby would not be likely to take more than *six drops*—certainly not more than twelve?" Just here is presented a very suggestive feature of the case. I quote from the published report of the casualty. "The doctor says he prescribed a smaller quantity of medicine than the clerk put up, his prescription reading 7.5 grammes. The decimal point was invisible and the clerk put up 75 grammes, a big phial full of the stuff—nearly two and a half ounces—instead of a little one. That made no difference so long as the directions for taking were observed, but Mrs. S—— would not have been likely to take so large a quantity out of the smaller supply."

Now it is well known that the practice is altogether too common of ordering medicines in much larger quantities than are likely to be used. It is an oft-repeated complaint on the part of patients, that the house is filled with bottles, boxes, and packages of "doctor's stuff" from which little has been used, the greater part of that purchased having to be eventually thrown away. This one little circumstance has been known to turn the scale in favor of such physicians as dispense from their own medicine-cases.

Another feature of this case is well calculated to surprise some of us. For years, the persistent advocates of the metric system have rung the changes upon the liability of confounding the drachm symbol (ʒ) with that for ounce (℥), thus leading to untold dangers to patients, assuming if not asserting that the adoption of the metric system would obviate the tendency to any such errors. Here, however, we are confronted with a case in actual practice, with a lapse in the use of the metric notation lying somewhere between the learned doctor and the skilled druggist. Evidently the overlooking of the decimal mark (.) works proportionally greater mischief than does the mistaking of the drachm and ounce symbols in the older method. And, although in this case the error was not the direct cause of death, it is easy to see that the same error in compounding a mixture would have been less easy to trace, and the innocent patient instead of the inquiring grandmother would have been the unfortunate victim.

I hardly need suggest how much more rational and safe it would have been to prescribe a two or three ounce mixture with water, making the proper strength of aconite to be given as desired. In this way no great amount of the dangerous drug would have been left about the house to endanger others. These may appear to be small matters, but in the use of powerful poisons, by either physician or patient, human life is involved, and it is not possible to be too cautious in matters apparently trifling.

I wish to call special attention to still another point. There can be little question that aconite is one of the surest, least painful, and most dangerous drugs that can be used for either homicidal or suicidal purposes. The difficulty of actual chemical detection, the rapidity of its action, the absence of any reliable antidote, and the fact that it is procured without much difficulty, and is kept as a domestic remedy in very many families, render this one of our most dangerous drugs. Some years ago I saw, under the care of another physician, a case in which an ignorant servant girl had been intrusted with some aconite by a dentist for the purpose of rubbing on her inflamed gums. The quantity, as he stated, was about a drachm of tincture of aconite root. Whether or not she mistook his directions and swallowed it by mistake, was never known. Suffice it to say that the next morning she was found paralyzed, and the bottle was empty. In spite of all our efforts she was never restored to consciousness, but expired within a few hours.

The public needs only a suggestion to put this knowledge to criminal use. On the very next day after the death of Mrs. S——, the New York papers recorded the death of a business man from New Jersey, who came to New York on one of his accustomed "sprees," and wound up by committing suicide with aconite. Undoubtedly he got his idea from reading the published report of the death of Mrs. S——.

The conclusions to be drawn from this case are so obvious that there is no occasion for further comment upon them.

Benjamin Edson, M.D.

Brooklyn, N. Y.

P. S.—When the foregoing was written I did not anticipate so speedy a confirmation of my warning. On Monday, September 15th, just two weeks after the death of Mrs. S——, Mr. R. T. Bush, a wealthy and well-known resident of Brooklyn, died suddenly from an overdose of aconite, evidently taken by mistake.

He was subject to insomnia and had been in the habit of taking paregoric for relief.

Feeling the need of sleep, about 6 A.M., he took from a bottle, supposed to contain paregoric, some three or more teaspoonfuls, which he put into some whiskey, and drank. The whiskey served to disguise the peculiar taste of the drug. Not experiencing the anticipated relief, and feeling some nausea and burning in the throat, he awakened his wife and told her of his suspicion that he had taken a dose of aconite. On examination, the paregoric bottle was found full, and the aconite bottle half emptied. Emetics and stimulants were at once given and the family physician called. He responded promptly, but arrived only a few moments before Mr. Bush breathed his last. The time from taking the fatal dose to his death was probably about one and one-half hour.

Powerful and poisonous drugs should be kept *only* in bottles of peculiar and suggestive form. Those of rough exterior and sharp-pointed glass-top stoppers are especially to be recommended. B. E.

SURGICAL TREATMENT OF POSTERIOR TURBINATED HYPERTROPHY.

To the Editor of the Medical Record.

Sir: In your issue of August 30th I see an article on the "Surgical Treatment of Posterior Turbinated Hypertrophy," by Dr. A. E. Prince, of Jacksonville, Ill., in which a pair of curved forceps are shown and a mouth-gag and an anæsthetic are recommended for the removal of such growths. Now I think the doctor's forceps are excellent, and in some cases the resort to an anæsthetic is necessary, and I would not be understood in any way as criticising

him, but it does appear strange to me that many of the profession still continue to use what may be termed "a blind method" of operating, viz., depending on the finger-tips in the posterior pharynx to guide the instrument, while by the use of a self-retaining palate retractor and a rhinoscopic mirror every step of the operation can be watched and accurately performed without the use of any mouth-gag, or anæsthetic except cocaine. We even occasionally hear that the old method by the "tape and clamp" is preferable for retracting the palate, while a more awkward and disagreeable operation both to the patient and operator can scarcely be imagined.

Yours very truly,

W. PEYRE PORCHER, M.D.

4 GEORGE STREET, CHARLESTON, S. C.

IN THE HEART OF THE NEW SOUTH.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: From the MEDICAL RECORD of June 5th it seems that some time during the early summer of this Anno Domini a very notable and momentous event took place in our pitiable (?) Magic City—a New York doctor *Wendt* all the way from New York City to our poor little village (?) on a professional visit, and he has taken large occasion to advertise the same. Well, perhaps it is worth speaking about.

Clean Clothes.—We are certainly a deplorable and to be pitied set of people down here who have to wear dirty clothes all our lives because we haven't a New York laundry to clean them. I suspect that he even thought that Colgate, and Graham & Palmer, and others are unknown here, and perhaps their products unused.

The Race Problem.—The unmistakable earnestness displayed in the "funny" doctor's solution of this question entitles his remarks to the pity of silence; that such a frivolous solution should be so earnestly given to so momentous a question—but the thought is certainly true to its parentage. But even if his solution were practicable would it not be best to reserve a few of the best and purest specimens for color, size, filth, and stink for the supporters of the Force-Lodge Bill, and perhaps the very best of them all for Ingalls to hang on the bridge of his spectacles (?).

The Medical Profession.—But the poor medical profession down here! May the Lord have mercy on them, but more especially may his mercy abound toward those upon whom they—our doctors—practise their stupendous ignorance. Why don't we send to New York for our doctor when our babies have the colic? (Some few specimens of them have life and vitality enough to have the colic and even to utter a feeble cry.) Or when our thin-breasted maidens have the time-honored ball in their thin throats which will neither down into their thin stomachs nor out through their thin lips? (It is a fact, Mr. Editor, that some of our maidens do have the physical strength, if not the common-sense, to have hysterics.)

And now, you poor Birmingham "consultation" doctor, who by right of years and experience, even-handed with educated brains, who have read after and studied under some of the greatest masters in this and other countries, are entitled to respect, let me say, "How are the mighty fallen!" you are devoid of all sense and observation compared to this scintillating and coruscant star that *Wendt* from New York to Birmingham, Ala. (Punning is a very low order of wit.) But he comes, a master of languages, gleaned largely, it seems, from the hinder part of the blue-back spelling-book; but our poor benighted city was illumined once in its life with a "consultation" doctor, and it is surely plain to a blind man that our poor, ignorant doctors here are not the only ones "haunted with the dreadful secret of their own pre-eminence."

Our Women.—Nothing so plainly shows such a deplorable lack of that culture and refinement by which we recognize and appreciate the beautiful than what the "funny" doctor who *Wendt* from New York to Birmingham has said. Our fair women, reared in the arms of a gentle mother clime, and kissed and fanned by her warm, gentle breath, that scarcely withers the delicate flower, whose vital forces need but the daintiest of delicate food, stand out pre-eminently, the acknowledged admiration of the world, whose beauty is transparent and transcendent. She can "dance all night and go home in the morning" as bright and as fresh as a new rosebud, and she moves with the dignity and grace of a "heave of the sea, or a change of the cloud." His "slander" evidently shows that he has been accustomed to and admires a beauty fostered by severe cold, olive-oil, limburger, and lager, and he don't want any other sort in his'n. (Am sorry I don't know any Latin.) Now to his letter in the RECORD of August 2d, I wish to speak to only one or two points in this. If he knows how to cure typhoid fever I wish he would tell us. Has his knowledge of the bacteria or microbe of typhoid given him any help in curing it? Has the knowledge of bacteriology added any force or strength to our therapeutics? Because he knows and can isolate the bacteria of phthisis can he cure the complaint? Then what is he talking about, except that he loves to see his name in print; who writes everything he knows and some things that he don't know, as I shall endeavor to show before I am through, and because he thinks he writes well and what he writes meets "with such a flattering reception."

These fevers have been written up for your journal, I think, and why has he formed no opinion concerning them? If they have not been written up, perhaps some of us poor, pitiable ignoramuses, who never write anything, should write them up. I cannot notice this point in his letter farther without going into the details of "this" fever and making this letter too lengthy—hence I dismiss it.

A Word of Warning Concerning Birmingham.—As strong as it is, I lack English to express my condemnation of this part of his letter. It is positively painful to a sensible man to see the "Ego," the "I am from New York" in his letters, but the positive, unadulterated ignorance displayed by the doctor who *Wendt* from New York to Birmingham, Ala., is simply pitiable. He says in B'ham's "present sanitary condition it is an excellent place to stay away from," showing palpably his mental "feather-weight" and want of observation, and that he came and comes to conclusion by premeditated intentions and not from thought or investigation. His slander is positively malicious, and I beg to append a few short plain statistics for the information of the gentleman.

We have twenty miles of the Waring system of sewerage.

We have two large crematories and every twenty-four to thirty-six hours every street and alley in our city are cleaned of all their filth and garbage and hauled to these crematories and there burned, and families are required to place in alleys accessible to these wagons all slops and garbage.

We have between three and four million gallons of water in daily use, brought here from what is known as Five Mile Creek, and which has its source among the eternal hills from whence comes the limpid sparkling waters that form this creek. It is pure and clean as any that ever gushed from mother earth. And not only that, but the necessity arising from our peculiar and magical growth for a greater water supply, we shall, by October next, have a large stream, five millions daily, from the Cahaba River, distance some seven miles from this city, and we tap that river not more than twenty miles from its source among the everlasting hills, and we get its water pure and uncontaminated.

Now, I challenge the doctor to refute this. Since the doctor has said that this is "an excellent place for white people to stay away from," I beg to add, the death rate of the whites for the first seven months of this-year: Census enumeration, 27,000. January, 12.84; February,

13.68; March, 13.68; April, 10.56; May, 16.08; June, 17.28; July, 13.32. Average 13.34.

Now, where is there a city in the United States can make a better showing for health than this?

J. H. McCarty, M.D.

THE NEEDLESS PRESCRIPTION OF SPECTACLES.

To the Editor of the Medical Record.

Sir: In your issue of July 5th Dr. Gifford writes, under the above caption, protesting against the wholesale prescription of spectacles, particularly for the young.

His statement that it is the practice of the majority of oculists to correct 0.75 D to 1 D of hypermetropia, and 0.25 D to 0.50 D of astigmatism, when there are eye symptoms "not otherwise easily explained," is undoubtedly true, and the doctor shows that he belongs to the majority when he admits that he sometimes prescribes a quarter dioptry cylinder, whether he does this for mental or physical effect.

It is generally in these nervous cases where these weak glasses are used, and with good effect. Where slight errors of refraction are found, with ocular disturbance not otherwise explained, the indication for glasses for constant use is clear. By the term "constant use" I understand that the glasses are used both for distant and near work. They may be so used for a few days or for a lifetime.

That reputable oculists prescribe glasses needlessly I do not believe, or, at least, it is to only a limited extent, and it seems to me that the doctor has failed to make out a case. I can now recall but one instance where I thought glasses were needlessly prescribed, while I can recall from memory as many as a dozen prominent citizens of Chattanooga who should wear spectacles, but have refused. Some of these are doctors.

It seems to me that his whole article is misleading. It conveys the idea that the majority of oculists prescribe glasses whenever there is a slight error of refraction, regardless of symptoms. This I believe to be far from the truth. The general rule is to adopt glasses as the last resort. Oculists realize fully as well as any the inconveniences and disadvantages of spectacles. They also know their advantages. Having determined that glasses are indicated, one of the hardest tasks in many cases is to induce the patient to wear them. The idea that people wear glasses for style is a thing of the past, for it is among stylish people that most difficulty is experienced. There are not a few cases where ladies admit that they would rather have severe headaches, and asthenopia with its attendant discomforts, than to put on spectacles. Nor is the male sex free from this species of vanity. Some are afraid that having begun the use of glasses they will have to wear them ever after. This will be the case if the original condition exists; but it often happens that glasses will assist in tiding over a temporary condition, and may be left off when the nervous system recovers its wonted vigor.

We have a duty to teach the laity the *proper* use of spectacles as a therapeutic agent as well as for the aid they give to sight. The doctor's assertions are entirely too sweeping, and I could not see them pass by without a protest, knowing that they would attract wide-spread attention, coming from so high an authority, and appearing in a journal of as large a circulation as the Medical Record.

Frank Trester Smith, M.D.

Chattanooga, Tenn., August 7, 1890.

Petition for a New College.—A petition, said to be signed by "a large number of prominent citizens," will be presented to the next legislature of Vermont asking for a charter for a new medical school to be started in Rutland. Even citizens are beginning to be interested in free medical treatment.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 14 to September 20, 1890.

Spencer, William G., Captain and Assistant Surgeon. By direction of the Acting Secretary of War, will upon the abandonment of Fort Bridger, Wyo. (his present station), report in person to the commanding officer at Fort Omaha, Neb., for duty at that station, relieving First Lieutenant Alfred E. Bradley, Assistant Surgeon. S. O. 214, par. 16, A. G. O., Washington, D. C., September 12, 1890.

Bradley, Alfred E., First Lieutenant and Assistant Surgeon. By direction of the Acting Secretary of War, upon being relieved by Captain Spencer, will report in person to the commanding general, Department of the Platte, for duty as attending surgeon at the headquarters of that department. S. O. 214, par. 16, A. G. O., Washington, D. C., September 12, 1890.

Sutro, William N., First Lieutenant and Assistant Surgeon. By direction of the Acting Secretary of War, leave of absence granted in S. O. 149, June 26, 1890, from this office, is extended fourteen days. S. O. 214, par. 6, A. G. O., Washington, D. C, September 12, 1890.

McElderry, Henry, Major and Surgeon. By direction of the Acting Secretary of War, the leave of absence for seven days heretofore granted by the Superintendent of the U. S. Military Academy is extended to November 10, 1890, on account of sickness. S. O. 214, par. 5, A. G. O., Washington, D. C., September 12, 1890.

Cochran, John J., Captain and Assistant Surgeon, now on duty at Fort Adams, R. I. By direction of the Acting Secretary of War, will proceed to Mount Vernon Barracks, Ala., and report in person to the commanding officer of that post for temporary duty, and on completion of the duty contemplated he will return to his proper station. S. O. 214, par. 2, A. G. O., Washington, D. C., September 12, 1890.

Ives, Frank J., Captain and Assistant Surgeon. By direction of the Acting Secretary of War, granted leave of absence for three months, commencing about October 1, 1890, provided one of the acting assistant surgeons serving in the Department of the Missouri can be assigned to duty in his stead at Fort Sill, Oklahoma Ter., during that time. S. O. 213, par. 26, A. G. O., Washington, D. C., September 11, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending September 20, 1890.

Olcott, F. W., Passed Assistant Surgeon. Ordered to the Alert.

An Indian View of the Benefits of Civilization.—The impending extinction of the Indian is not viewed with equanimity by all belonging to that race. Here is the speech of an aged warrior, recently reported: "Before the white man came, we were strong—we were alive! We lived in tents, we rode on horseback, we moved constantly from place to place. We ate good meat of buffalo and juicy venison; we drank pure water. Our young men never coughed, the blood never sprang from their lips; our girls had not these great swellings on their necks and these pale faces. The white man brought us these things! He brought us the flesh of diseased cattle, bad bacon, the coffee that takes away our strength. We sit in the white man's houses and eat these things, and we die like the dogs! There are no old men and old women nowadays; the very children are dying!"

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 20, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	52	17
Scarlet fever	23	8
Cerebro-spinal meningitis	1	1
Measles	41	6
Diphtheria	53	20
Small-pox	0	0
Varicella	2	0
Pertussis	17	1

Differential Diagnosis of Injuries about the Hip.—The following table has been prepared by Dr. Keen as an aid to the differential diagnosis between dislocation and fracture of the neck of the femur.

Fracture of Neck.	*Dislocation.*
Old persons, as a rule.	Adult middle life.
In women more frequently.	Either sex (men more frequently).
Slight force.	Severe force.
Eversion of toes.	Inversion of toes (usually).
Shortening in both.	Shortening in both.
If you restore to position displacement recurs.	If you restore to position displacement does not recur.
Usually crepitus.	No crepitus.
Preternatural mobility.	Preternatural immobility.
Slight prominence of great trochanter.	Great prominence of great trochanter.

He also gives this table as a differential diagnosis between intra-and extra-capsular fracture of the neck of the femur.

Intra-capsular.	*Extra-capsular.*
Slight injury.	Severe injury.
Rarely severe contusion.	Usually severe contusion.
Shortening increases.	Remains the same.
Crepitus feeble and sometimes absent.	Crepitus distinct.
Leg nearly (but not entirely) helpless.	Entirely so.
Shortened radius of rotation.	Still more so.
Pain tolerably severe.	Extremely severe.
Usually occurs in persons over fifty years of age.	Usually occurring in persons under fifty years of age.
More frequently in women.	More frequently in men.

—*College and Clinical Record.*

The Congo Cannibals.—Father Augouard, Apostolic Pro-Vicar of the Oubanghi, states that it is his intention to found a station upon the Upper Oubanghi, 1,100 miles from the coast, among the anthropophagous tribes with whom the slave is regarded simply as an article of food. He gives some curious information as to these tribes, remarking that while in certain parts of Africa cannibalism only exists as an incident of war, to deprive the vanquished of even the honor of burial, in the Oubanghi country human flesh is an article of regular consumption, not a day passing without a village immolating some victim destined to provide a feast. Sometimes it is the death of a chief, at others the celebration of a victory, at others the arrival of a piece of good news, which serves as a pretext, and one chief will vie with another to see which can immolate the most victims. These savages regard human flesh as a dainty morsel, and prefer it to any other food, considering that it is a noble kind of food, far superior to that of animals. When told that it was horrible to eat their fellow-creatures, they simply replied: "No, it is delicious with salt and spices." When Father Augouard went on to point out to them the difference between man and the animals, and to say that if they fell into the hands of their enemies they might be eaten in their turn, all they said was that that was the fate of war, and that, just as man was nobler than animal, so his flesh was "more noble to eat."—*London Times.*

Snow in the Treatment of Venereal Sores.—Dr. Wettendorfer has contributed a curious experience of his in the *Internationale Klinische Rundschau.* In a case of venereal ulcerations of the penis the ordinary remedies used in such cases were employed without being attended by any results. Remembering that many of the people of Hungary treat frostbites, ulcers, etc., with applications of snow, he resolved to give this curious method of treatment a trial in his venereal cases. He caused a small wooden vessel to be filled with snow in such a manner that a hollow space remained in the snow to admit the penis. The whole was attached to the body by means of bandages. The snow was renewed every two hours. In about eight days the ulcerations had entirely healed.—*St. Louis Medical and Surgical Journal.*

Effects of Castration in the Female.—The following experience of a veterinary surgeon is of interest in relation to complete removal of the ovaries in our own species. M. Barthelmy states in the *Journal ae Médecine Vétérinaire,* that œstrum or "rut" can occur in pigs after complete removal of the ovaries. A professional spayer operated on thirty-eight young pigs under sixty days old, yet these animals showed the symptoms of "rut" at from three to eight months, and monthly after that age, as though they had not been spayed. An action was brought against him after M. Barthelmy had given his opinion that the œstrum indicated incomplete removal of the ovaries. The defendant declared that he had seen œstrum in pigs which had been properly spayed. The court ordered that five of the pigs that showed all the phenomena of œstrum to the greatest extent should be killed and examined by a competent veterinary surgeon. This was done, and it was found that in each case the operation had been well performed, the ovaries, tubes, and almost the entire cornua of the uterus having been removed.—*British Medica Journal.*

The Rationale of Cold Baths in Typhoid Fever.—M. Debove, in a paper read at the last session of the Paris *Société Médicale des Hôpitaux* on the treatment of typhoid fever by cold baths, declared that he had not been convinced by a recent paper of M. Merklen that this was the best treatment. His own mortality during the last six years was eleven per cent., or during the last two years 9.2 per cent. Now Mr. Merklen estimates the mortality from typhoid in Paris hospitals treated by cold baths as 9.92 per cent. M. Debove does not prescribe active medication, but believes in keeping up copious diuresia. To this end he supplies his typhoid patients with abundance of liquid, and if the quantity of urine passed does not appear to him sufficient, he "stimulates the zeal" of the attendants to get the patient to drink more; the total amount of fluid which should be taken daily ought, he says, to be not less than five or six quarts. M. Debove, who does not deny the good effects of baths, suggests that they are probably due to the increased quantity of urine secreted, which, as in the case where diuresis is produced by drinking, carries off the *materies morbi* from the system. According to M. Gérin-Rose, who followed M. Debove, still more successful results may be obtained by carrying out the following indications: 1, To produce intestinal antisepsis by means of naphthol and salicylate of bismuth; 2, to lower the fever by means of very large doses of quinine and warm baths (at 86° F.); and, 3, to keep up the patient's strength. Of forty-three patients treated during the last eighteen months in this way, only one died.—*The Lancet,* August 16, 1890.

A Universal Panacea.—The acting colonial surgeon of the Victoria Hospital, in Gambia, states that, among the inhabitants of that country, there is but one recognized treatment of disease. This consists in calling in a man who is supposed to be a "doctor," and who, after looking at the patient, sits down at his bedside and writes in Arabic characters on a wooden slate a long rigamarole, generally extracts from the Koran. The slate is then washed, and the dirty infusion drank by the patient.

INTUBATION OF THE LARYNX IN ACUTE AND CHRONIC SYPHILITIC STENOSIS,

AS A SUBSTITUTE FOR TRACHEOTOMY AND THE METHOD OF SCHROETTER.[1]

BY GEORGE M. LEFFERTS, M.D.,

PROFESSOR OF LARYNGOSCOPY AND DISEASES OF THE THROAT, COLLEGE OF PHYSICIANS AND SURGEONS, NEW YORK.

FROM among many matters, of more than passing interest, concerned with the subject to which I have been assigned, there is none which, in my judgment, possesses a more recent one, nor is of greater scientific value and pressing and immediate importance, than that of "intubation" in certain syphilitic diseases of the larynx.

I have, therefore, selected this question for consideration, and shall advance clinical evidence in support of the effectiveness of the method, which, though it is as yet limited, comprises all that I am either personally familiar with, or have learned by a careful bibliographical research, and which leads to certain definite results that merit attention, based as they are upon established facts and not upon speculative theory.

Intubation, in the treatment of diphtheritic croup, revived, improved, and popularized by American genius and perseverance, must soon, by its very simplicity, readiness, marvellously quick relief in moments of urgent danger, and brilliant, ever-improving statistics of cure, find a world-wide acceptance and become universally practised. Already a method, doubtfully adopted in America in 1885 but by a few, now numbers its confident and enthusiastic operators everywhere, and its successful cases by the hundred. Such evidence must be regarded as sufficient that the procedure is founded upon some inherent merit.

On the contrary, our knowledge of intubation as a means of relief or cure in other forms of acute and chronic laryngeal stenosis, especially those of syphilitic origin, is in its infancy, its ultimate possibilities as yet undeveloped.

A more extensive practical trial and possible improvements, in both method and instruments, will doubtless more than confirm what our present limited experience has tanght concerning its value.

Confining myself, then, to the question of syphilis alone, intubation certainly offers, in a large proportion of instances, the simplest and most practical means yet devised of quickly and efficiently relieving the dyspnœa of acute laryngeal stenosis, thus avoiding a tracheotomy, and for dilating chronic cicatricial stricture, in its varying grades and forms, with speed and certainty, thus dispensing with the temporary or permanent necessity of a tracheal cannula.

The history of the treatment of chronic laryngeal stenosis, especially that of a cicatricial nature, shows no brilliant triumphs and but few lasting successes. Many methods have been devised, many instruments been the outcome of the inventive ingenuity of specialists; but until the latest and well-known one of Professor Schroetter, which necessitates the existence of a tracheotomy wound, no distinct plan of procedure had, or has since, been formulated.

[1] A paper read before Settion XII. of the Tenth International Medical Congress, in introducing a discussion upon "Syphilis of the Upper Air-passages."

A short research in medical literature tells of the varied procedures of, among others, Alexich, Asch, Busch, Bergmann, Caird, Chiari, Czermack, Gerhardt, Gurlt, Hering, Hack, Labus. Macewen, McSherry, Nawratil, Polk, Richet, Ribemont, Rauchfuss, Semeleder, Schroetter, Stoerck, Sceparowicz, Trendelenburg, and Weinlechner, the majority of whom passed the dilating instrument through a tracheal wound upward into the strictured larynx.

In other instances attempts were made to relieve the laryngeal stenosis by the use of a long tube or catheter passed through the mouth, or sometimes the nose, into the larynx, an unsatisfactory method for many reasons.

Trendelenburg, followed by Schroetter, employed the hollow, three-cornered, or a round vulcanite bougie, or catheter, as a dilator, and this, in turn, was superseded by the graduated and solid metal one, as now used in tracheotomized patients in the justly celebrated method of Schroetter, one so well known as to its details of procedure, advantages, disadvantages, and results that it needs no description here.

For the relief of sudden, severe, and dangerous dyspnœa, occurring in the course of a syphilitic laryngitis, the operation of tracheotomy, the one usually chosen, has been heretofore our single resource. One that, though it temporarily relieves, adds perhaps to the original condition of danger others, *i.e.*, shock, loss of blood, an open wound, erysipelas, septicæmia, or those dependent upon any procedure that opens up the great air-passages, or the operation of laryngotomy, which, in addition, directly exposes the delicate articular and muscular apparatus of the larynx to risk and permanent disability, especially if the cannula be long retained.

No rule is absolute, no plan of procedure infallible; but with these older methods of treating laryngeal stenosis the newer one of intubation may be favorably compared. For tracheotomy it offers an efficient substitute devoid of danger, and in view of the special features, one more effective and reasonable.

Over the "method of Schroetter," the only one necessary to be considered in this connection, it presents the advantages of avoidance of the necessity of a preliminary tracheotomy, and affords a possibility of the continuous and prolonged retention, without risk or inordinate discomfort, of the dilating means.

Doubtless the future will modify, perhaps greatly extend, the limitations here placed upon the procedure, but to-day we may claim certainty of fulfilment in some, reasonable expectation in others, of the following general indications.

Some, therefore, I advance with confidence, others with hesitation, but submit all for your candid criticism.

CLASS I.—The immediate relief of dyspnœa in all cases of acute syphilitic stenosis of the larynx, by mechanically and temporarily affording an artificial passage for the respiratory current through the intubation-tube.

CLASS II.—Facilitating and hastening, by either equitable and prolonged, progressive, or specially directed pressure of the intubation-tube, the absorption of acute inflammatory effusion, or the thickening and induration attendant upon chronic syphilitic inflammation of the larynx.

CLASS III.—Forcible dilatation and continuous distention, by means of the intubation-tube, of slight and recently organized membranoid or band cicatrices.

Class IV.—Progressive dilatation, by means of a series of intubation-tubes, of cicatricial strictures of the larynx, subsequently to their incision, by some form of cutting laryngeal dilator.

Class V.—Divulsion and progressive dilatation: Incision and subsequent distention, the former being made through the larynx, or from below, through the tracheotomy wound; or systematic, continuous dilatation, by such specially adapted intubation-tubes as may be required in cases which vary greatly in the nature, extent, and character of the lesions, in all cases of chronic and extensive cicatricial stenosis of the larynx, with displacement and distortion of laryngeal parts, the result of dense cicatrization following gummatous degeneration in tertiary syphilis and where a tracheotomy tube may or may not be worn.

And in the following classes:

Class VI.—In dyspnœa due to abductive immobility of the vocal cords, dependent upon syphilitic non-suppurative adhesive arthritis of the arytenoid articulations, or their mechanical-fixation by either plastic infiltration of the tissues in their neighborhood, leading to adhesive perichondritis and spurious anchylosis, or cicatrices of the same parts, which bind them in an immobile position, and in which well-directed pressure by the intubation tubes will exert a favorable influence in promoting absorption of effused material, or forcibly break up cicatricial attachments and free articular movement.

Class VII.—In dyspnœa dependent upon abductor paresis, from commencing degenerative processes of syphilitic origin in the abductor muscles themselves, in which the preservation, by means of the intubation-tube, of even a small respiratory opening may stimulate normal physiological movement and preserve nutrition by maintaining muscular activity.

It is understood that in all the above classes of cases intelligent and energetic anti-syphilitic treatment is employed to combat the accompanying diathesis; and that the tracheotomy cannula, if it be worn, is no contra-indication or barrier to the use of an intubation-tube.

Practical illustrations of many of these propositions are afforded in the histories of the following cases, which are condensed as far as is practicable consistently with clearness:

Class I., Case I. *Acute Syphilitic Stenosis of the Larynx; Condylomata.*—Lizzie S——, aged twenty-six. The involvement of the larynx has existed three and a half months, and severe dyspnœa progressively and rapidly developed. An examination of the organ shows its cavity to be completely occluded by a large, irregular, reddish mass, whose attachments cannot be defined.

The danger of suffocation being imminent, a medium-sized metal intubation-tube was introduced without difficulty. The relief was immediate and positive; no inconvenience was caused by the presence of the tube, and on the third day it was removed. Respiration was free and unimpeded. The occluding tumor had shrunken to a small and unimportant size, and its remains were seen as small reddish granulations, specially in the posterior commissure.

An examination made two years later (May, 1890) shows the lumen of the larynx to be free, the muscular movements of the vocal cords normal, the right slightly thickened and reddened, and the tissues in the posterior commissure hypertrophied and irregular.[1]

Class I., Case II. *Acute Syphilitic Stenosis of the Larynx; Subglottic Laryngitis; Gumma.*—A syphilitic patient, aged forty, and aphonic, developed a dyspnœa so urgent that all preparations for a tracheotomy had been made. The laryngoscope showed subglottic laryngitis (perichondritis). A long intubation tube was passed through the strictured portion of the larynx without difficulty and with immediate relief. The tube was removed in five days, but replaced in twenty minutes, owing to the rapid return of the dyspnœa. Two days later it was again withdrawn, and reinserted in half an hour; and for the third time, ten days after the first insertion, when it was left out for twenty one hours; dyspnœa then became so urgent that it was hurriedly replaced and not disturbed for twenty-one days from the first introduction, when it was withdrawn and the patient found to breathe comfortably without it.

Six weeks later the patient was found deeply cyanosed and rapidly becoming asphyxiated. Examination showed the dyspnœa to be due to the presence of an intralaryngeal gumma. Intubation was immediately performed, with some difficulty; relief to the dyspnœa followed; the tube was not disturbed for one week, then removed and replaced by a larger; the latter was worn seven days and then permanently withdrawn.

Three years have now elapsed (May, 1890) since the last intubation, and no repetition of the procedure has been necessary; the larynx shows some subglottic thickening, which interferes to a slight degree with both the voice and respiration.[1]

Class II. Case III. *Chronic Syphilitic Stenosis of the Larynx; Hypertrophy; Ulceration; Chronic Œdema.*—Mrs. M——, aged forty-five. The patient gives a specific history. Four years ago she first complained of painful sore-throat, referable to the larynx. There had been difficult breathing for two years, increasing until the present dangerous grade of dyspnœa had been attained. The epiglottis is partially destroyed by old ulceration; the cavity of the larynx is almost entirely occupied by dense, indurated, and swollen mucous membrane, intensely hyperæmic; secondary œdema of arytenoids, and partially of the ventricular bands. No view of the glottis region is obtainable. From the left ventricle of the larynx a small, soft mass, apparently granulation tissue, protrudes; complete aphonia. Intubation, under cocaine anæsthesia, with some difficulty and force; the smallest-sized rubber tube, fairly well borne, remained in position eighteen days. The relief to the urgent dyspnœa was marked and immediate. Upon the removal of the tube, doubtless owing to the continuous intralaryngeal pressure exerted, there was considerable increase in the calibre of the laryngeal cavity; the parts were more clearly defined and fair motion of the vocal cords existed. No reintroduction of the tube was, or has been, necessary.

The patient has made progressive improvement both in respiration and voice.

Nine months later (May, 1890), voice fair; no return of the dyspnœa, and continued increase in the breathing space through the larynx.[2]

Class II., Case IV. *Chronic Syphilitic Stenosis of the Larynx; Ulceration; Hypertrophy.*—The patient, aged twenty-two, with emaciation, hoarseness, cough, and dyspnœa at night, showed active ulceration at the base of the epiglottis and upon the left side of the larynx. General hypertrophy of the laryngeal tissues, and specially of the arytenoids, which latter were partially anchylosed. The dyspnœa was progressive, and within five months had become urgent. Three intubations, within two days, with successive increase in the size of the tubes, relieved the dyspnœa; one week later it was necessarily repeated, and a much larger tube retained comfortably for eighteen days before it was expelled. Respiration now but slightly embarrassed. After an interval of three months a slight recurrence of dyspnœa was relieved by the use of a large-sized tube for twenty-four hours. For a period of nearly three years subsequently the patient was under observation; there was no diminution in the size of the glottic opening, and no recurrence of dyspnœa. He died ultimately of an affection unconnected with the throat.[2]

Class III., Case V. *Cicatricial Stenosis of the Larynx.*—A patient, aged forty, with the soft palate adherent to the posterior pharyngeal wall; active ulceration, the epiglottis partially destroyed and deformed by cica-

[1] New York Medical Journal, February 22, 1890.

[1] New York Medical Journal, March 10, 1888.

[2] Ibid., February 22, 1890.

tricial contraction, and a cicatricial band encircling the left half of the larynx, crossing and partially occluding the glottis anteriorly; cicatricial adhesion of the ventricular bands. Gave a syphilitic history of twelve years' duration, and one of serious dyspnœa for two months; patient aphonic. A small intubation-tube was passed with force through the constriction, and gave immediate relief to the dyspnœa. This was succeeded in rapid sequence by other and larger tubes during eighteen days, until ample breathing space existed in the larynx. Tubes inserted nine times, and retained an aggregate of one hundred and seventy-three hours.

Two and one-half months later intubation again became necessary, owing to a gradual return of the dyspnœa, due to an inflammatory subglottic stenosis. Dilatation was recommended with the smallest tube, introduced with force, and rapidly followed by larger ones, for twenty-seven days. Tubes inserted thirteen times and retained two hundred and four hours. Relief to the dyspnœa was again prompt.

Ultimately, practical trials having demonstrated that periodical introduction of the intubation-tubes was necessary, certainly for a time, to retain the degree of dilatation obtained, a large rubber-tube was inserted once a month and worn from two to three days; these intervals were gradually extended until seven months had elapsed, when all treatment was discontinued. One year and eight months (May, 1890) have since passed. There is now not the slightest difficulty in respiration; voice excellent.

Class IV., Case VI. *Cicatricial Stenosis of Larynx.*—A girl, aged eighteen, the victim of hereditary syphilis, has had destruction of the nasal septum, perforation of the hard palate, ulceration of the pharynx, and later, despite an active anti-syphilitic treatment, complained of increasing dyspnœa, due to a gradual closure of the glottis, "without ulceration."

Dilatation with Schroetter's bougies gave but temporary relief, and tracheotomy was performed, followed in the course of time by the use of Whistler's cutting dilator. Through the enlarged opening thus made in the cicatricial tissue a small intubation-tube was passed with some difficulty. A second and larger one was introduced in three days, and worn over one month; a further and too rapid increase, from the third to the eighth in size, was followed by a perilaryngeal abscess. A tube was finally allowed to remain unremoved for three months. A free opening through the glottis, the size of the tube, now existed, and respiration being easy and natural, the latter was not reintroduced. The tracheotomy-tube, which had for some time been worn closed, was permanently withdrawn in less than one month from this date, and the tracheal wound closed.

A report, six months later (April, 1889), shows that freedom in respiration continues; no vocal cords can be seen; patient speaks in a loud whisper.[3]

Class IV., Case VII. *Cicatricial Stenosis of Larynx.*—A female, aged thirty-five, syphilitic, showed on laryngoscopic examination a syphilitic adhesion uniting the anterior two-thirds of the vocal cords and involving the cushion of the epiglottis. The glottic opening was reduced to the size of a goose-quill. Dyspnœa marked. Under an anti-syphilitic treatment the inflammatory conditions that coexisted subsided.

The cicatricial stenosis was treated by dilatation with the rubber intubation-tubes, worn for two weeks at a time, and their size progressively increased.

Two months later, improvement in the general condition of the patient and in her breathing being most decided, dilatation was discontinued.

A lapse of two months and the patient reappeared, complaining of an increasing dyspnœa, which was shown to be due to a recontraction of the cicatricial web.

Cocaine anæsthesia and division of this cicatrix, with Browne's laryngeal dilator with cutting blades, the introduction of hard rubber intubation-tubes of increasing size, at intervals of three days, until seven days had elapsed and the edges of the divided tissues found to be healed over, were now practised.

Again two months have passed without treatment, the cicatricial web has diminished, the glottic opening is free, and remains so, the patient in excellent condition and breathing at a normal rate.[1]

Class V., Case VII. *Chronic Syphilitic Stenosis of the Larynx; Bilateral Paralysis Abductors; Cicatricial Adhesion of the Vocal Cords.*—The patient, a woman aged thirty-five, had worn a tracheotomy tube for two years for the relief of dyspnœa, due to bilateral abductor paralysis of syphilitic origin. A forcible attempt, under ether, to pass a small metal intubation-tube through the larynx failed. The wound in the crico-thyroid space was then enlarged and a uterine sound forced through the adhesions found binding the inferior surfaces of the vocal cords together; the opening thus made, dilated by forceps and finger, allowed the passage of an oval rubber tube, three inches long, from above through the larynx.

The laryngotomy wound was now closed, and the patient breathed through the natural passages. On the second day the intubation-tube was coughed out, the patient became asphyxiated, and the cannula was necessarily reintroduced; the tube was immediately replaced and cannula again removed.

Some weeks later the necessity of removing some tissue, in order that a permanent cicatricial opening, for respiratory purposes, might be permanently retained, became apparent. A portion of each vocal cord was cut away by a knife introduced through the original, but enlarged, laryngotomy wound. The intubation-tube was replaced, and a closed tracheotomy cannula temporarily introduced, but in a few days finally removed and the wound closed. At the end of eight days the former was withdrawn for a day and a half, the patient breathing easily through the larynx. Eleven days later it was withdrawn for three days, and subsequently, owing to the difficulty encountered in replacing it on each occasion of its periodical removal, a longer interval was determined upon. A cylindrical metal tube was now inserted in the larynx, with the intention of removing it in one month.

After a lapse of ten months and four days the patient reappeared; the metal tube was in position, and worn comfortably; respiration unembarrassed. The tube was only removed by force, being encrusted with coarse granules of calcareous matter. The presence of some granulation tissue caused slight embarrassment in respiration, which quickly disappeared on removal of the cause; the intubation-tube was not again introduced, respiration remaining perfectly free.

An examination of the larynx, made some months later, showed that a large cylindrical opening existed at the glottic level; no trace of the vocal cords was visible; the external laryngotomy wound appeared as a deep sulcus; the cough was toneless, and the voice, as before, a distinct whisper.

The patient, a dissolute and unreliable person, ultimately disappeared from observation, the intra-laryngeal conditions remaining the same as above noted.[2]

Class VI., Case IX. *Acute Syphilitic Stenosis of the Larynx; Perichondritis; Anchylosis of Arytenoids.*—Louise S——, aged thirty-five; shows a cicatrix at the junction of the hard and soft palates. Hypertrophy and ulceration of the ventricular bands extending posteriorly below the right vocal cord, with secondary œdema. Within six and a half months dyspnœa had become excessive and dangerous. The cavity of the larynx was occupied by swollen, reddened, mucous membranes, which rendered any identification of its individual parts impossible; on the right side, posteriorly, ulceration. A small rubber tube was introduced with difficulty and force, but imme-

diate relief to the dyspnœa. On the sixth day the tube, badly borne, was removed, and the laryngoscope showed marked subsidence of the acute intralaryngeal swelling with resultant free respiratory space. For the following seven months progressive improvement occurred. A lapse for two months in the regularity of the constitutional treatment was followed by a return of the dyspnœa, now seen to be due to an immobility in abduction of the vocal cords from fixation of their arytenoid cartilages.

Nine months after the first intubation a second became necessary, and during a moment of impending suffocation a medium-sized rubber tube was introduced without difficulty between the closely approximated vocal cords. Relief was immediate. On the fourth day the tube was coughed out and not replaced, the grade of dyspnœa being but slight. The laryngoscope now showed, aside from some unimportant local lesions, fixation of the right vocal cord in the median line, and immobility of the right crico-arytenoid articulation. The left vocal cord, though sluggish in abductive movement, performed its physiological functions with progressive improvement.

The conditions here described have remained unchanged more than one year since the second and last intubation.[1]

Case X., *Chronic Syphilitic Laryngitis; Bilateral Paralysis of the Abductors.*—Mrs. G——, aged twenty-six, with a probable, but not actually proven, syphilitic history, has suffered from severe attacks of dyspnœa at intervals during the past two years. The present urgent attack had lasted fifty-six hours; the patient was comatose, with stertorous breathing. A view of the larynx, obtained with difficulty, showed paralysis of the abductor muscles of the vocal cords, with a dry and swollen laryngeal mucous membrane. Intubation, practised as soon as possible with a small rubber tube, easily introduced, gave instant relief, and was worn ten hours, when it was removed by the partially delirious patient. Two hours later a second intubation was successfully performed, and the ensuing relief lasted six hours, when the temperature rose to 104° F., respiration 60, and pulse became imperceptible. Death followed from heart-failure in the course of beginning pneumonia.

The late date in the laryngeal disease at which intubation was practised robbed the operation of its possible benefits.[2]

I have elsewhere reported (*New York Medical Journal*, December, 1878) two cases of bilateral abductor paralysis of syphilitic origin, in which the timely use of iodide of potash effected a cure. In more urgent instances intubation will not only fulfil the indications set forth in Class VII., but will afford safety to the patient during the period of administration of the drug and the establishment of its physiological and remedial effects.

I do not propose here to discuss the details of procedure, many and varied, that are essential to render the operation of intubation a success. In American literature, especially, will be found the records of a rich, practical experience, which has laid bare many faults, suggested many modifications, and taught many valuable lessons; the outcome of these, our knowledge of to-day, will be communicated to you by Dr. O'Dwyer, whose name, is so widely and justly identified with the subject, and whose large personal experience renders him most competent to perform the task.

Certain modifications of the accepted method on the child are necessary when operating upon the adult; changes in the tubes and in the rules for their use exist; to these it is necessary that I should briefly allude.

No rule can be absolute either in theory or practice. Intubation in acute syphilitic stenosis is usually readily accomplished, and, as the cases herewith prove, successfully attains its object; but the management of chronic stenosis, so varying in its nature and indications for treatment, will always require patience, perseverance, and ingenuity. Both demand a manual skill only attained by practical experience.

The operation of intubating the larynx of the adult presents certain obstacles that do not pertain to the same operation in the child. One of these is caused by the depth at which the adult larynx lies from the mouth, and the difficulty, often impossibility, of introducing the finger which guides the tube over the epiglottis or upon the arytenoid cartilages. Specially is this true in those cases where a tracheotomy-tube has been worn for a length of time and the inactive larynx does not rise to meet the finger.

Again, the very lesions which render the operation necessary in the syphilitic larynx, especially in the extreme grades of cicatricial stenosis, present a barrier to the easy introduction of the tube that does not exist in the diphtheritic larynx of the child. Not only does the exertion of considerable physical force become necessary to overcome these barriers, but much delicate manipulation, based upon a careful study of the requirements of the special case, is requisite. In order that the object of the intubation may be successfully attained, the laryngoscopic mirror may afford aid in guiding the earlier stage of introduction of the tube, but the forefinger of the left hand will always be required ultimately as a means of its propulsion into the laryngeal cavity until the thickest portion of its retaining swell has passed well below the vocal cords, in order that it may be retained as and after the "obturator" has been withdrawn; the mirror is thus necessarily relinquished. On the contrary, the laryngeal mirror will be found of service in the adult when the "extractor" is subsequently used to remove the tube from the larynx.

The large size of these tubes is no contra-indication to their use. Experience has amply shown that while the greatest variations exist in the sensibility and degree of toleration to the presence of the tube exhibited by different larynges, less danger of injury from pressure by the large tubes exists in the adult with chronic infiltration of the tissues, or stenosing cicatrices, than in the child whose larynx is occupied by the inflammatory infiltration, prone to succumb to ulcerative action of diphtheritic croup. For this reason the large tubes can be worn by the adult with more safety, less frequently changed, and retained continuously for lengthened periods.

A practical trial in individual cases will determine the exact limit of these periods; but it is safe to assume, as a general rule, that in cases requiring a tube to be long retained, specially if this be a metallic one, the points of pressure in the vestibule of the larynx shall be changed about once in two to three weeks. Erosion of the mucous membrane and exuberant granulation tissue can thus usually be prevented.

The larger head that accompanies the increase in the size of the intubation-tubes required for the dilatation of stricture accomplishes these changes until the maximum-sized tube is reached, when the points of dangerous pressure may be still further changed by slightly increasing the thickness of the head, especially upon its under surface and in a vertical direction, leaving its diameter the same. The intubation-tube is thus raised from time to time in the larynx.

Other modifications to attain the same end will suggest themselves to a mechanical genius.

Two practical points to be furthermore borne in mind are, that the series of tubes shall be used in slow and gradual progression, increasing at not more than the rate of one thirty-second inch in their antero-posterior diameter, and that much depends, in the first instance, upon the selection of a proper size to commence the series, usually the smallest that will permit of easy respiration, and one that shall fit well down in the larynx without becoming fixed or impacted, and which will therefore allow of some slight movement during the physiological act of deglutition, experience having proven that the compression of the laryngeal constrictor muscles about the head

[1] New York Medical Journal, February 22, 1890. [2] Ibid.

of the badly fitting and too movable tube during this act is a prolific source of erosion and granulation tissue.

As in children, early difficulty in deglutition is a prominent complication in the adult; the latter, however, owing to the longer periods for which the tubes are retained, usually learns to overcome it completely.

Schluck pneumonie has, thus far, not been experienced as a possible consequence in any case of intubation in the adult.

The intubation-tubes for the treatment of laryngeal stricture that I here exhibit will be seen at once to vary in many important details from the same tubes as employed in children. As at present constructed the series consists of ten tubes, the larger made of hard rubber alone; the medium sizes of brass, gold plated, and with vulcanite heads in order that their weight in the larynx may be lessened; the smaller tubes are made of metal only; a special "introducer," with long curve to compensate for the decreased length of the intubation tube, and, as well as the "extractor," made larger and more strongly than the same instruments as used in the case of the child, complete the equipment.

Our experience is not as yet absolute, but tubes made of hard rubber will ordinarily be found to be most satisfactory and best tolerated by the patient. They are light, do not readily become impacted by the swollen tissues, cause less injurious pressure, allow of easier respiration, permit expectoration of the accumulated secretions, and are therefore less liable to become occluded, do not erode nor invite the deposit of calcareous matters, as metal ones do. For these reasons they are probably best fitted for prolonged sojourn in the larynx.

I have selected one of the most stirring and practical questions of the day concerned with syphilis of the throat, and one on which there is, at this time, good reason to expect progress from very wide discussion. The chief need seems to be the collection of facts well observed by many persons. By many, not only because many facts are wanted, but because in all new research it is well that each apparent fact should be observed by many.

Errors that I may have made in my conclusions will have their utility, for errors, like doubts, serve to bring out the truth and show its value. Certainly we may look for the attainment of some novelty and change in our present knowledge concerning the treatment of acute and chronic syphilitic stenosis of the larynx, and after every such change there must ensue a change in some of the conditions of thinking and working. To effect these changes, and in favor of intubation, has been the object of my task.

TWO CASES OF PERITONEAL HÆMATOCELE OF UNUSUAL DIMENSIONS TREATED BY ABDOMINAL SECTION.[1]

By GEORGE M. EDEBOHLS, A.M., M.D.,

GYNECOLOGIST TO ST. FRANCIS HOSPITAL, NEW YORK.

DURING the past eighteen months three cases of large peritoneal hæmatocele have come under my observation, two of them retro-uterine, one ante-uterine. Two of them appeared to me worthy of record on account of the very large size of the blood-tumors and their treatment by abdominal section. Incidentally, the verification of the condition by the treatment adopted proved of interest as placing the diagnosis beyond a doubt.

CASE I.—Philomena M——, aged twenty-eight, married at twenty-four. One year after marriage she gave birth to a dead child at the end of the eighth month of utero-gestation. Fifteen months later she was delivered of a living child at term.

Menstruation has always been regular, lasting four to five days, up to December, 1888. On the seventh day of that month a period was due and came on as usual. The flow, however, ceased at the end of the first day. Two weeks later, on December 21st, she was taken with sudden metrorrhagia, chilly sensations, fever, and severe abdominal pains. The abdomen at the same time rapidly enlarged. She came under my care on January 16, 1889. Her general condition seems good; she is well nourished, and not at all anæmic in appearance. The abdomen is distended to the size of a nine months' gestation by an irregularly shaped, distinctly fluctuating tumor, with rather indistinct outlines. The larger portion of the tumor is situated to the left of the median line. Circumference of waist, forty-seven inches.

The lower end of the tumor can be reached with some difficulty from the vagina, high up above the left vault. Uterus appears slightly enlarged; it is displaced forward and slightly to the right.

The tumor fills the entire abdomen with the exception of the right lumbar region, the right hypochondrium, and the epigastrium. In the left hypochondrium the dulness is continuous with that of the spleen, in the left lumbar region with that of the left kidney. In the middle line the tumor reaches as high as the lower end of the sternum.

Exploratory puncture through the abdominal walls, at two widely distant parts of the tumor, yields a dark-red, serous fluid. Under the microscope this fluid is found to contain a few crenated blood-corpuscles, about twice as many leucocytes, a few isolated epithelial cells, and a large number of fat-corpuscles. Examination of the urine gives negative results.

The results of the microscopical examination pointed directly to hæmatocele. Against that diagnosis stood the blooming appearance of the patient, and the enormous size of the tumor. A hæmatocele of this size has, to my knowledge, never been described. A cystic tumor of the left kidney, or of the left ovary, with intracystic hemorrhage, was considered the more probable diagnosis. The large number of fat-cells found on microscopical examination led me to lean to the diagnosis of cystoma of the left ovary, partly, at least, dermoid in character.

The pressure symptoms caused by the large size of the tumor called for relief, and on January 22, 1889, assisted by my colleague, Professor John H. Ripley, I performed abdominal section.

An incision was made in the median line, commencing one inch above the umbilicus, and extending six inches in a downward direction. Upon incising the peritoneum we at once entered a large cavity filled with the bloody fluid above described, of which four and one half to five quarts (4,300 to 4,700 c.c.) were evacuated. The recesses of the bottom of the cyst were filled with a dense sediment composed of red blood-cells. The reason why so few red blood-cells were met with in the examination of the fluid removed by exploratory puncture was now apparent. With the patient lying on her back the blood-cells gravitated toward the deeper portions of the cyst, beyond the reach of the exploring needle. The sediment of blood-cells was scooped out with the hand and flushed out by free irrigation with sterilized water.

The walls of the cyst were formed anteriorly by the abdominal parietes; above, on both sides, and posteriorly by coils of intestine glued to each other by firm and thick adhesions; inferiorly, by the pelvic organs. The interior of the cyst-wall was everywhere lined by a layer of coagulated fibrin one half to one inch in thickness. The uterus, slightly enlarged, could be distinctly felt through the cyst-wall, displaced forward and slightly to the right of its normal situation.

The cyst-cavity was thoroughly irrigated until the fluid returned clear. Two rubber drainage-tubes, each half an inch in diameter, were inserted through the lower angle of the wound. The rest of the wound was closed with silkworm-gut sutures.

Patient rallied well. The cavity was irrigated twice daily with sublimate solution, 1 to 5,000, and rapidly di-

[1] Read before the Gynecological Section of the Tenth International Medical Congress.

minished in size. At various periods very large patches of the fibrinous layer became detached from the interior of the cyst-wall and were extracted through the abdominal opening.

February 20th.—While the cyst was being washed out patient suddenly went into collapse. This was followed by an enormous gush of blood from the vagina. Examination showed the cervix dilated; the finger passed within discovered the presence of a fœtus of about three and a half months. As prompt interference was necessary to check the alarming hemorrhage two fingers were passed into the uterus and the placenta entirely detached from the uterine wall. Thereupon the bleeding ceased, and labor pains came on. Twelve hours later the fœtus was found in the upper part of the vagina and removed.

On February 27th the patient left hospital for home, with a small drainage tube still *in situ* in the almost-obliterated cavity of the hæmatocele. The patient disappeared from observation and I have been unable to learn anything of her since.

CASE II.—Annie J——, aged forty-two, married, has always menstruated regularly and painlessly since the age of seventeen. Duration of flow seven days. She was married at twenty-two, had one miscarriage in 1889, and gave birth to six living children. Date of last confinement, as well as of beginning of present illness, March 13, 1890.

Patient and her husband are both very unintelligent, and the history obtained was not at all as clear as desirable. The following are the facts, as far as I could elicit them: Our patient has not felt well since her last confinement. The abdomen did not return to its normal size, but remained swollen and somewhat tender. Pain on voiding urine and obstinate constipation were the other prominent symptoms. For two days after the birth of her child she passed clotted blood. Then the bleeding ceased entirely and did not return until May 13th. On that date a vaginal hemorrhage appeared which she regarded as a normal period. Instead of lasting seven days, as usual, the flow suddenly ceased on the second day. Coincident with this, the large abdomen enlarged still further, with return of the abdominal pain formerly experienced. On May 17th she came under my care.

Patient looks anæmic and wears a set, anxious expression. Pulse rapid, 100 to 110; temperature normal. The abdomen is distended by a distinctly fluctuating tumor, filling its lower and central portions, and reaching upward, in the sitting position, to a point four inches above the umbilicus, and two inches below the xiphoid cartilage.

The outlines of the tumor are indistinctly defined. It is nearly circular in shape, mesial in situation, and twelve inches in diameter. Patient measures thirty-four inches around chest, forty inches around waist. Per vaginam the tumor can, with very great difficulty, be reached anteriorly and high up on the left side. Through the left vaginal wall a structure resembling a normal ovary in size and consistence can be distinctly felt applied against the inferior aspect of the tumor. Cervix large and patulous, in approximately normal position. The uterus lies retroverted, with the fundus turned slightly to right, along the inferior and posterior aspect of the tumor. The sound enters to the depth of three and one-half inches. The tumor is ante-uterine, occupying the peritoneal fold between bladder and uterus.

Exploratory puncture at two points of the tumor distant from each other yields, at both places, fluid of a deep Burgundy-red color. Microscopical examination shows an abundance of red blood-corpuscles in a shrivelled condition, with a few leucocytes and epithelioid scales.

Diagnosis, ante-uterine peritoneal hæmatocele. The tumor having lately increased in size, and the pressure symptoms being urgent, laparotomy was proposed, accepted by the patient, and performed on May 24, 1890.

A small incision, one and one-half inch long, was made in the median line, just below the umbilicus. After opening the peritoneum a semi-organized layer of blood and coagulated fibrin, one-fourth to one-half inch thick, was encountered, lining the interior of the peritoneal sac, and loosely adherent to the latter. It was just firm enough to permit of suturing it with catgut to the edges of the peritoneal wound. A curved trocar was then plunged through the fibrinous layer and eighty-six ounces (2,543 c.c.) of bloody fluid were evacuated. The trocar opening was enlarged by the finger and two handfuls of quite recent blood clots were turned and washed out. No macroscopical evidence of an ovum or fœtus was encountered. The layer of coagulated, dark-red fibrin was found to completely line the interior of the cyst-cavity. The upper, lateral, and posterior walls of the latter were formed by the lower surface of the mesentery, and by intestinal convolutions firmly adherent to each other. Below, the left ovary could be felt through the sac-wall in its normal situation, as also the uterus displaced posteriorly and somewhat to the right. The right ovary could not be felt.

After thorough irrigation a double rubber drainage-tube was inserted into the cavity and the small abdominal wound closed around it. Two days later the dressings were changed and the drainage-tubes removed.

The fluid gradually reaccumulated until the abdomen was distended almost as greatly as before operation. On June 7th the wound reopened, and a gush of thin red fluid was discharged. The wound then closed again, to be reopened by over-distention two days later. This process was repeated a number of times from June 7th to June 24th, the bloody serum reaccumulating until the pressure separated the lips of the abdominal wound and the distention was temporarily relieved by the escape of the excess of fluid. During all this time strict asepsis was maintained, and the patient's temperature never went above the normal.

On June 24th I reopened, under ether, the entire length of the abdominal wound. I then passed my finger into the cyst and along its anterior wall to the left. Here, four inches from the median line, upon the finger-tip as a guide, I made an incision one inch long through the abdominal wall into the cyst-cavity. This procedure was repeated on the opposite side, making a third opening into the cyst-cavity, four inches to the right of the median line. The evacuated fluid, of a lighter red color than at the first operation, measured about seventy ounces (2,070 c.c.). It contained no fresh coagula, nor anything indicating that a hemorrhage had occurred since the first operation. The fluid seemed to be mainly a secretion from the cyst-wall, which on its way to the interior of the cyst, through the deep red fibrinous layer, abstracted sufficient coloring matter from the latter to give it a decidedly red tinge. This supposition was strengthened by the appearance of the fibrinous coagula lining the cyst-wall. Whereas at the first operation they were deep red, almost black in color, they now presented a colorless and blanched appearance.

A large quantity of this fibrinous layer was stripped off by the fingers and removed. Two drainage-tubes were carried, one from each lateral wound, through the hæmatocele along its anterior wall, and out at the central incision—so that one end projected from each lateral, and two from the central opening. To prevent the drains from slipping in, the ends of each were fastened together across the intervening integument by a strand of silkworm-gut. The abdomen, which before operation measured forty inches in circumference, now measured thirty-two inches.

Less and less fluid was evacuated through the drainage-tubes daily, until July 2d, when the drains were finally removed. The lateral openings through the abdominal parietes closed immediately. A small fistulous track, discharging a small amount of pus remained in the abdominal walls at the site of the median incision. As it did not extend into the abdominal cavity, it was expected to

close very soon. Abdomen did not refill, the intestines coming up well against the anterior abdominal wall, as denoted by the percussion note, and the patient was discharged, cured, July 15th. Two weeks later all the open ings were found firmly closed.

Antisepsis, or rather asepsis, was carefully maintained throughout the entire progress of the case. The patient's temperature remained absolutely normal from the date of first operation until the day of discharge.

As already stated, I have thought it worth while to place on record these two cases of hæmatocele on account of the great size attained by the tumors, and because in both the diagnosis was verified by operation.

One was retro-uterine, extended upward to the processus ensiformis of the sternum, and contained over nine pints (4,300 c.c.) of fluid. The patient measured forty-seven inches around the abdomen. This constitutes a larger hæmatocele than any of which I have been able to find a record.

The other was ante-uterine, extended to four inches above the umbilicus, and contained eighty-six ounces (2,543 c.c.) of bloody fluid. The patient measured forty inches in circumference at the waist.

In fifteen of Voisin's cases the tumor was six times four finger-breadths below the navel; six times three finger-breadths below the navel; two times one finger-breadth below the navel; one time five finger-breadths below the navel; and in one case even two finger-breadths above the navel.[1]

T. Gaillard Thomas:[2] "Abdominal palpation will reveal the presence of a hard mass which may extend only up to the superior strait, or as high as the navel."

A. Martin[3] and L. Tait[4] make no allusion to the size that may be attained by hæmatoceles.

C. Schroeder:[5] "Nimmt man die äussere Untersuchung vor, so fühlt man entweder in der Mittellinie oder am häufigsten links, seltener rechts, einen rundlichen, über die Symphyse hervorragenden Tumor, der unter Umständen bis zur Nabelhöhe hinaufreichen kann."

Ely van de Warker:[6] "These (hæmatocele) cavities are of a great variety of forms and have a capacity of one-half pint to five pints." No other allusion is made to their size.

T. A. Emmet:[7] "When a hæmatocele is formed within the peritoneal cavity it may slowly enlarge and extend out of the pelvis, on the side of rupture, to above the line of the umbilicus." Emmet, however, does not describe or refer to a case of the kind.

A. J. C. Skene:[8] "Abdominal palpation, made after the tympanitic distention has subsided, will often show the mass extending to the superior strait, and even higher, and in one case that I saw the blood-clot extended upward half-way to the umbilicus."

J. Mathews Duncan:[9] "A large, prominent swelling occupied the whole of the lower half of the belly, extending up to within two inches of the umbilicus."

Charles West[10] describes "a tumor (hæmatocele of left side) extending three inches above the umbilicus, reaching about two inches across the mesial line, although gradually sloping downward, so that on the right side its upper margin was an inch and a half below the umbilicus." And again, "a tumor, the surface of which was slightly uneven, occupying the whole of the left side." In this latter case, which ended in recovery, the circumference of the abdomen measured forty-six inches. It shrank to forty inches on leaving hospital.

F. E. Beckwith[1] writes: "Barnes records one case which contained 946 c.c. (2 pints). Duncan tapped below the umbilicus and drew off 3,401 c.c. (115 oz.) of lymphy blood, the case ending in recovery. I have drawn off per vaginam 828 c.c. (28 oz.) from one situated behind the uterus, the case ending in recovery."

The above quotations, although by no means exhaustive, will serve fairly well to indicate the size of the largest peritoneal hæmatoceles that have been recorded.

I do not believe that the amount of fluid contained in either of my two cases above narrated represents exactly the quantity of blood actually lost. On the contrary, I am of the opinion that the clinical histories, both before and after operation, warrant the belief that a great, if not the greater, part of the fluid was made up by serous effusion from the irritated peritoneum forming the cyst-wall. We know that a subacute peritoneal inflammation usually follows the effusion of blood into the peritoneal cavity. This peritonitis is conservative, gluing together the intestines, encapsulating the blood already effused, and by pressure upon it tending to check further hemorrhage. Under ordinary circumstances the peritoneum in contact with the effused blood forms the best possible surface for the absorption of the latter; but when the peritoneal irritation exceeds a certain limit, instead of peritoneal absorption peritoneal effusion takes place and adds to the bulk of the tumor.

This certainly appeared to be the case in both the above instances. After a perfectly aseptic operation the fluid in one case continued to form and discharge though the drainage-tubes for five weeks. In Case II. the hæmatocele was thoroughly irrigated and emptied, and the abdominal wound practically closed two days after operation. In twelve days the fluid had reformed in almost the original quantity and burst open the abdominal wound. This reaccumulation and discharge continued for seventeen days longer, when the second operation demonstrated the absence of hemorrhage following the first laparotomy, and thus proved the fluid to have been derived by secretion from the cyst-wall.

In regard to the treatment of the larger hæmatoceles that come under our care, I feel that the question cannot be considered as positively settled—in other words, that no hard-and-fast rules of treatment applicable to every case can be laid down.

Much depends, in my opinion, upon the certainty of diagnosis in each particular case, and upon the tendency exhibited by the tumor to increase or decrease in size. When the tumor shows a tendency to diminish in size, the more we leave to nature and the less we do ourselves, the better for our patient. The perfect absorption and disappearance of even large blood tumors has been observed again and again, and is illustrated in the subjoined Case III.

When the tumor, instead of decreasing, keeps on gaining in size, active interference is called for. Where, as in Case II., the diagnosis can be made with great positiveness, and where percussion demonstrates that the tumor reaches well up against the anterior abdominal wall, I would be inclined to advocate evacuation of the fluid contents of the tumor by the aspirator, followed by firm compression of the abdomen. With a perfectly sterilized aseptic needle, with careful asepsis of the abdominal parietes and of the operator, I do not believe this procedure involves the least danger. The disastrous results recorded as following this simple procedure were due to the methods prevailing in the preantiseptic era, or to want of sufficient care to secure asepsis in more recent times.

If the fluid reaccumulated after the first evacuation by the aspirator, I should be inclined to repeat the aspiration a second and a third time. When repeated refilling demonstrates the futility of further continuance in this course incision and drainage are clearly indicated.

Where the tumor reaches the anterior abdominal wall,

[1] Reference Handbook of the Medical Sciences, edited by A. H. Buck, vol. iii., p. 451.

I should always prefer to open through the latter, rather than through the vagina, inasmuch as I would feel more certain of being able to maintain asepsis of the tumor contents. In both of my cases the tumor, if at all, could have been reached from the vagina only with the greatest difficulty.

When, as in Case I., the diagnosis is in doubt, and the urgency of the symptoms calls for interference, laparotomy is the only course to be considered. This will enable us to clear up the diagnosis and at the same time to apply the proper measures called for by the nature of the case.

By way of illustration of the rapidity and thoroughness with which the natural powers of absorption, unaided, often dispose of even large accumulations of blood in the abdominal and pelvic cavities, I append the following :

Case III.—Mrs. Mary M——, aged thirty-six, married and the mother of thirteen children, came under my care March 29, 1890.

On June 14, 1889, she gave birth to her last child. Menstruation returned in November, 1889, and recurred regularly until February, 1890. On February 15th, on the third day of a period, the flow suddenly stopped. One week later she began to flow again, and lost a considerable quantity of blood daily for the next five weeks, when she came under my care. I may here add that this hemorrhage continued until April 3d, when it ceased spontaneously.

Patient, however, barring the hemorrhage, had nothing especial to complain of until March 27th. On that day she began to feel pain in the rectum, near the anus, and in the lower part of the back. She was unable to sit with comfort, and was harassed by a bearing-down sensation, a constant desire to defecate, and a sensation as of a weight in her pelvis. Pain on micturition and diminution in the amount of urine were also noticed. Urine is of a pale amber color, specific gravity 1.014, acid, and contains granular casts.

Examination reveals a large fluctuating tumor occupying Douglas's sac. It reaches downward to within two inches of the perineum, and extends upward to within one inch of the umbilicus. The uterus is crowded forward against the pubis by the tumor. Exploratory puncture per vaginam yields blood. Diagnosis, large retro-uterine hæmatocele.

During the following two weeks the tumor diminished rapidly in size from day to day. A slight and steady elevation of temperature and free diuresis accompanied the process of absorption, constituting the condition known as sapræmia.

April 20th.—Tumor almost entirely absorbed, a slight retro-uterine thickening being all that can be felt.

May 2d.—Entire disappearance of tumor. Absolutely nothing left to indicate its former presence.

The patient received absolutely no medication of any kind, not even a placebo. Her large retro-uterine hæmatocele was absorbed by the unaided powers of nature in from four to six weeks.

198 Second Avenue.

MICRO-ORGANISMS AND LEUCOCYTES—OUR PRESENT STATUS AS TO EACH.

By EZRA M. HUNT, M.D., LL.D.,

secretary state board of health, n. j.

Whatever may be the diversity of judgment as to the relations of micro-organisms and of leucocytes to disease or health, no one can have failed to note great changes of view and what we must at present regard as real progress of doctrine. Some of these changes may be briefly noted as follows :

(*a*) When micro-organisms began to be recognized as having some relations to disease, they were not recognized as having equally important relations to health. Most of the prominent bacteriologists now concede that there are three separate studies of micro-organisms, viz., those which relate to the benign organisms in their conservative and indispensable relation to health, those which relate to septic or saprophytic organisms in their relations to decaying matter, and those which relate to pathogenic organisms in their specific relations to disease.

Each of these has already developed wonderful lines of study, but not enough as related to each other, or in due proportion, since more attention has been concentrated on pathogenic micro-organisms than upon the others.

Next, the study of the products of micro-organisms has become of very great importance. In relation not only to ptomaïnes and leucomaïnes but also in all the wide field of vital and chemical changes, we do not yet know how much results from products or how far these results are dependent upon individual and local conditions. M. Bouchard, in his Berlin address on "The Mechanism of Infection and Immunity," says that the anti-bacterial condition is not a dynamic or vital, but a chemical quality of normal, healthy blood, which unfits it for being a life-medium for bacteria.

(*b*) Next, the positiveness as to the number of diseases which are caused by micro-organisms, and especially by pathogenic forms, is undergoing marked change. Take such recent authorities as De Bary, Klein, Koch, Sutton, Crookshank, Vaughan, etc., and we find that the specification of the diseases of which the specific organism is known is both narrowed and varied (see article, *Medical News*, March 17, 1888). Since that record Dr. Koch, in his address at the International Medical Congress, specifies as settled only anthrax, tuberculosis, and erysipelas. Sir W. Foster, at the recent meeting of the British Medical Association, puts anthrax and relapsing fever as the two diseases in which we know a specific micro-organism, and tubercle and cholera as probable. Sutton would include glanders, and Vaughan, as we shall hereafter note, shows the probable origin of many so-called specific diseases from various micro-organisms instead of any one singly. Crookshank raises the question, long since incidentally raised by Sir William Jenner as a practitioner, whether what is attributed to specific micro-organisms is not mostly, if not entirely due to septic varieties. The recent paper of Professor Vaughan, of Michigan, on "Some New Bacterial Poisons," *Medical News*, August 16, 1890, we regard as a most important contribution to the literature of medical bacteriology. While recognizing that cholera infantum, for instance, is related to the presence of germs, he also claims that "the number of varieties and species is confusingly great, with no constancy in the presence of any of them. . . . These germs, which differ from one another sufficiently to be classified as different species, form poisons, which also differ in chemical properties, but which produce the same symptoms and post-mortem appearances."

We believe a great modification of belief is probable as to the relation of this or that particular or specific germ to the causation of communicable diseases.

(*c*) Nor are bacteriologists speaking with their former positiveness as to the probability that the exanthemata and other diseases, such as influenza, pneumonia, etc., are dependent upon a specific microbe. There are strange facts as to the relation of the microbe of erysipelas to diphtheria (Prudden, etc.), and as to what Koch would call "deviations of demeanor," but what others would call varied organisms (see Klein, Crookshank, Sutton—in "Evolution and Disease," Scribner, 1890—Vaughan, etc.).

Dr. Koch raises a question as to the probability of bacteria being the cause of malaria, yellow fever, pleuropneumonia, whooping-cough, etc. He also doubts whether hydrophobia and Pasteur's inoculations belong to bacteriology, although "grown on its soil."

Those who have been so sure that the finding of causal and specific bacteria in all contagious diseases was only a question of time, and have confidently predicted such an origin of pneumonia, influenza, etc., must see that there

is lately a decided spirit of "judicious scepticism." The fact that so many diseases not found to be parasitic are communicable, and that so many found associated with micro-organisms are not, is leading to greater guard in asserting the *materies morbi*. As one expresses it, "It is by no means certain that a pathological medium is created, but the microphyte selects one ready to hand."

It is somewhat peculiar, also, that just at this time, amid the tendency to increase the catalogue of communicable diseases, there seems to be cumulative evidence that diseases once regarded as contagious may not be so. Thus, besides the testimony as to the non-contagiousness of leprosy from various other sources, we have the experiments and long experience of Dr. Beaven Rake, Superintendent of the Trinidad Leper Asylum. In his annual report for 1889 he says that he is not prepared to admit that leprosy is contagious in the ordinary sense of the term, and answers various evidences to the contrary that have been alleged.

(*d*) We also think that there is some progress toward the belief that forms of pathogenic micro-organisms are not necessarily original or immutable, and that environment, both within and without, has great influence. Although Dr. Koch says it has been ascertained that one form of bacteria is not transformed into another, this prevalent view is by no means so settled as it has been or as he would indicate.

We think J. Bland Sutton ("Evolution and Disease," 1890), who shows such accurate and intelligent ability as a student of life in its varying forms, is nearer the truth when he says, "The history of micro-organisms shows clearly enough, as in the case of animal parasites, that pathogenic bacteria have been slowly evolved from non-pathogenic forms and have slowly acquired the power of flourishing upon living bodies when the environment is suitable." No doubt many of them have become so specialized, like the gentian's among plants, as to have all the permanency of non-pathogenic forms, but not so with very many. The possibility of reversion under discouraging environment is more hopeful than relief by vaunted germicides. No one can have followed closely the various preventive inoculations of Pasteur, or the facts as to kine-pox, horse-pox, and variolation from man, recently brought out by Crookshank (all of which seem to prevent variola), without suspecting that new facts are still to break forth as to the origin and behavior of micro-organisms under different environments or amid the presence of varied vaccines. "The more," says Sutton, "these questions are studied the more we perceive that the outbreak of infectious diseases depends not so much upon the presence of micro-organisms—for like the torula they seem to exist everywhere—as upon the existence of suitable conditions; and as yeast cannot grow and multiply without sugar, neither can the poison of erysipelas, typhus, relapsing fever, and the like propagate without the presence of some substance produced in living bodies, of the nature of which we are ignorant" ("Evolution and Disease," 1890, page 225).

Rodet and Roug, from their studies of Eberth's bacillus, conclude that, while found in enteric fever, it is only a degenerate form of the bacterium coli commune which is constantly present in the healthy intestine. Those of us who have long held to the occasional *de novo* origin of typhoid fever are finding new evidence of its probability.

We are aware with what positiveness some bacteriologists reject this view of change amid environment, but not so the biological naturalist and various practitioners who have opportunities for the study of infective diseases where there are better opportunities for localization and study of environment than in cities and hospitals, and where a thorough knowledge of chemistry and botany throws light upon the laws of life.

(*e*) Although an early result of the germ theory was also a therapeutic theory as to curing diseases by germicides, it has become quite apparent that this assertive practice has been relegated to the rear. As a recent editorial in the *Medical News* says, "Germain Sée and Jourmon admit that all endeavors to find a parasiticide which would destroy the bacillus tuberculosis and allow the patient to live have proved futile. Creasote is the only medicament which has retained the slightest credit in this direction, and it is extremely doubtful whether even this has any direct influence whatever upon the life of the microbe. When it has a good effect, this is to be attributed to the favorable influence which it exercises upon the character of the secretions. The problem, therefore, is reduced to the best means of rendering the tissues invulnerable." This latter clause is really an admission that the microphyte does not create the pathological medium but selects it. While, however, it is not probable that medication by germicides will hereafter be sustained, there is still hopefulness in attempts to prevent disease by the use of a class of remedies that are aseptic. There are some reasons for believing that iron, potassium chloride, creasote, and various other medicaments interfere with the processes of disintegration and so prevent or arrest the development of some diseases. It is one thing to claim this action as germicidal, and another to recognize the inhibiting influence of certain medicines or of certain nutritive and hygienic measures.

Next we note the study of leucocytes as related to micro-organisms and the progress in this direction.

For some time after the discovery of the white corpuscle there were very indefinite views as to its origin, its mode of production, and the service done by it either in physiological or pathological conditions. One by one new facts have been elicited, some of which may be said to be settled. So far as their relation to micro-organisms is concerned, they have come to be regarded as playing some important part after their escape from the capillaries. Their relations to inflammation and fever, and their active participation in diseases such as those occurring about the tonsils, where they are present in abundance, is maintained by many pathologists.

The more recent experiments and opinions of Metschnikoff seem to us to have thrown new light on the subject. It is true that Dr. Koch in his Berlin address says that the opinion that the white blood-corpuscles resist the bacteria is more and more losing ground.

On the other hand, Sir Joseph Lister, on the same occasion, emphasized "the scavenger cells or phagocytes discovered by Metschnikoff; the white blood-corpuscles which envelop parasitic intruders and render them harmless." While Ziegler and Graewitz give more prominence in inflammation to tissue corpuscles as distinct from the exuded leucocytes, they do not explain away the facts as to the actual conservative work done by the leucocytes upon septic or pathogenic micro-organisms.

The whole subject is well presented in Chapter X. of the book of Sutton already alluded to. The whole chapter, as a convenient statement of doctrine, will well repay perusal. We only quote that part relating to these white corpuscles or leucocytes and micro-organisms: "This aggressive behavior of leucocytes to foreign bodies is extended to such unwelcome guests as pathogenic bacteria. When micro-organisms effect an entrance into an animal the leucocytes attack and attempt to destroy them, and the details of such amœbic warfare may be described from attacks actually witnessed by Metschnikoff in the water-flea (daphnia). This observer kept many of these interesting transparent creatures in a tank, and noticed that they became affected with spores, which gained an entrance into the body of the crustacean, germinated, and were dispersed by the blood over the body (in daphnia the blood circulates in lacunar spaces) and deposited in those parts where the blood moves slowest, viz., in the cephalic and hinder portions of the mantle cavity; in these places heaps of conidia collect. In the meantime the leucocytes do not remain idle against the invasion, but attack and devour the conidia, take them into their interior and digest them. If a conidium be too much for

one cell others join it, form a giant-cell and thus struggle with the invader. Should the leucocytes overpower the spores, the daphnia lives; if not, the conidia overrun the crustacean and death is the result.

"A similar process takes place in animals more highly organized, and as no disease illustrates more thoroughly the defending power exercised by leucocytes than that known as avian tuberculosis, the leading points in this widespread affection will be briefly considered. Tuberculosis in man is unfortunately very prevalent, but in birds, especially those which live on grain, it is more common than in human beings. On examining a bird which has died of this disease we find the liver and intestines presenting numerous rounded nodules of a pale yellow color, varying in size from a pin-point to that of a filbert. On cutting into the larger nodules the centre is found occupied by pus. The smaller ones are homogeneous, and on examining them microscopically we recognize in the centre small circular cells with larger ones—giant-cells—lodged among them, outside these a layer of smaller cells with no giant cells, and lastly a layer of fibrous tissue.

"When such specimens are suitably stained, minute rod-like bodies—bacilli—are seen clustered in the centre of the mass and occupying the interior of the cells, especially the giant-cells. In nodules of moderate size the centre is occupied by caseous material surrounded by a zone of cells containing bacilli. Adjacent nodules may coalesce and thus produce large masses. The blood-vessels connected with the nodules frequently present clusters of bacilli in their interior. An extensive and prolonged study of this disease has convinced me that the bacilli, from whatever source arising, are introduced into the alimentary canal and find their way into the walls of the bowel. Here they are attacked by the leucocytes, which surround, ingest, and destroy them. The bacilli may be too numerous for the leucocytes, and the point were the bacilli gain entrance into the tissues becomes a battle-field; large numbers of leucocytes are quickly on the spot, and reinforce their comrades; as a result of this encounter many of the leucocytes die, others fuse together and form giant-cells; the dead leucocytes form pus-cells and give rise to the caseous centre in the nodules, while along its confines, in the bacilliferous zone, the conflict continues to rage. The giant-cells are powerful antagonists, for I have seen one contain as many as fifty bacilli. From these nodules the bacilli are conveyed by blood-vessels, or even carried away by the leucocytes, and initiate new struggles in distant parts. It must also be remembered that, after their introduction into the body, the bacilli will, if the conditions of the host be favorable, multiply very rapidly, and in due course overrun the whole system—nodules arise in the liver, lungs, brain, and skin, function is interfered with and death results. In addition to the local troubles the invasion of an organism by bacteria produces general disturbances, one of the most important being an increase of the temperature of the body, usually termed fever."

The presence of certain proteids antagonistic to harmful proteids in the blood or tissues also aids in this work.

We deem it important, especially, that practitioners of medicine should realize how views are being thus modified as to microphytic diseases, and how much of what is discussed by some as if known is still in the range of speculation. It is all the more important because practitioners, while responding to all real proof as to contagion and need of isolation, disinfection, etc., are now beset by ultra-contagionists, who prescribe a degree of manipulation and isolation wholly impossible in general practice, and which does not actually prevent the presence of bacteria. Rigid conformity to real facts must be sought, but some do not seem to realize that there are many ill results from the agitation or enforcement of restrictions founded upon incomplete evidence.

Who shall decide when doctros disagree? The coroner.

Clinical Department.

THE TEPID BATH AS A SEDATIVE IN YOUNG CHILDREN.

By BOARDMAN REED, M.D.,

ATLANTIC CITY, N. J.

In the MEDICAL RECORD of September 13th there was reported a case of hyperpyrexia treated successfully by the tepid bath. The cure was prompt and striking, but the measure resorted to was not a novel one for the purpose of reducing high temperature. It occurred to me, however, during the past summer, to administer tepid baths to infants suffering from entero-colitis, with the extreme restlessness and pain which often accompany that affection. I was led, at first, to try this remedy because of the failure of all usual methods of controlling pain and restlessness in the case of a sick child. Below is a brief report of this case:

Case I.—An infant, aged eight months, was sent to Atlantic City in the early part of July on account of entero-colitis of several weeks' standing. The child was much emaciated, had a temperature of 100° to 101° F., and besides considerable diarrhœa was suffering more or less every day from severe attacks of what seemed to be colic. The family physician at home had ordered a mixture which I found to contain an unusually large dose of opium for so young a child. I inferred from this fact that the child had been suffering long and acutely, so that smaller doses of the opiate had failed. I permitted the same mixture to be resorted to whenever very severe pain should recur.

Not long after the case came into my hands the mother, in the middle of the night, sent a messenger to me with a note stating that the child was having terrible attacks of pain which nothing would quiet. I sent a quarter-grain tablet of morphia, with instructions to dissolve it in eight teaspoonfuls of water, and give one teaspoonful every hour until the pain should be quieted. Next morning, at ten o'clock, I found the child had taken nearly all of the quarter grain of morphia and yet the pain had not been fully quieted. It had slept an hour or two, but awoke again restless and uneasy. Not caring to give any more narcotic medicine at that time, and fearing that the child might go into convulsions, I ordered a tub half full of warm water to be brought in and had the child given a bath. The water was at a temperature of about 90° F. While the child was immersed in it, I had its head kept cool by cloths wrung out of cold water. The effect was magical.

Within ten or fifteen minutes the child quieted down, and on being taken from the bath fell off into a quiet, healthful sleep which lasted several hours. The diarrhœa was improved at the same time, and the little patient, from that time, began to get well. The mother and nurse having learned the value of the tepid bath, resorted to it afterward whenever the child was threatened with one of its "colic" spells. Within a week or two from the time of the first bath the little one had entirely recovered from the attack of entero-colitis. During the past summer I have resorted to the same measure in several other cases, and nearly always with like excellent results.

Dr. William Blair Stewart, of Philadelphia, who has been associated with me in practice during the summer, has also found the tepid bath a useful resource in cases of pain and cerebral complications associated with bowel complaints, and has kindly contributed to this article one particularly striking case, which will be found below:

Case II.—On July 11, 1890, I was called to see a little girl, aged fourteen months, who had been suffering from an attack of true cholera infantum for several days. The child had been treated with home remedies by its mother and grew steadily worse. From the mother's statement I learned that the attack began with violent vomiting, purging, and fever. The child became pale and weak, and when I saw it, two days after the onset of the attack, it

was lying in a comatose state with a temperature slightly above 101° F. A bath of about 90° F. was ordered and the child was immersed in it to the neck. At the same time cold water was applied to the head and a mustard plaster to the back of the neck. The bath was continued for about fifteen minutes. By this time a great change had taken place, for the child had roused up from its stupor and appeared much brighter in every respect, and had a temperature about normal. It was wrapped in a blanket to prevent its taking cold, and fell off into a calm sleep. After treatment consisted of one-hundredth-grain doses of calomel and ipecac, with one-quarter-grain doses of the sulpho carbolate of zinc. Diet was regulated, and the child recovered in the course of one week and is now a strong and thriving baby.

The above cases show that baths may be made especially useful in some of the acute diseases of children, and that tepid baths, under proper precautions, may exert a very marked sedative influence. Every practitioner knows the dangers of opiates when pushed unduly in the case of young children, and especially the risks involved in intrusting such medicines to inexperienced and excitable nurses. I am now fully convinced that the tepid bath is a most efficient sedative, particularly when there is cerebral irritation, and that it is probably at least as sure as any of our ordinary anodyne remedies in the control of abdominal pain in young children, after the bowels have been thoroughly opened so as to remove offending causes such as partly digested food.

In treating babies with indigestion, or any of the ordinary forms of intestinal disease, I always provide for thoroughly emptying the alimentary canal, at least once in two or three days, by giving a light dose of spiced sirup of rhubarb or other suitable mild laxative. Hereafter, when this has been attended to, and the pain, fretfulness, and restlessness persist, I shall direct prompt resort to the tepid bath.

A SIMPLE SUBSTITUTE FOR BELLOCQ'S CANNULA AND ALL OTHER METHODS FOR CONTROLLING EPISTAXIS.

By W. W. PARKER, M.D.,
RICHMOND, VA.

THE plan of arresting hemorrhage from the nose, which I here describe, I have used for thirty years without one failure. When I first began practice I used Bellocq's instrument, but I found it painful, and, in small children, exceedingly troublesome of application. Two months ago a man, twenty-three years old, in this city, was operated upon for irregular septum (a small part of the bone was removed), which was followed by troublesome hemorrhage. The operation was by a very skilful specialist, who, upon application of the patient the day after the operation, plugged the posterior nares with difficulty. But the hemorrhage persisted for three days, when the patient, whose father's family I had attended for many years, applied to me in company with his father. I, of course, declined to have anything to do with the case, and urged him to return at once to the specialist, who could do everything that was necessary. This he positively refused to do, and said if I would not attend him he would get some one else. He had visited the doctor three times, but the bleeding continued. As it was ten o'clock at night when he came to my office, I told him I would stop the bleeding and would see his doctor next morning and get him to call at the patient's house. This I did. I stopped the bleeding at once, but kept the patient and his father in my office till twelve o'clock at night to see if the hemorrhage really was arrested. This was the last of the bleeding. This man was of a hemorrhagic diathesis, and, some three weeks after this, he had hemorrhage from the lungs, which has continued occasionally up to this date. At the Red Sulphur Springs of Virginia he gained twenty pounds, but the bleeding from the lungs continued. He is of a phthisical family. I have been thus particular so that I might satisfy the reader that this was a bad case of epistaxis.

My plan is not only effectual, but is easy of application and absolutely painless, and can be probed in the smallest patients. The little device which I use is made of fifteen of the long threads of patent lint, size three and one-half or four inches long, which I double on themselves and tie in the middle, and let one end of the string be six or eight inches long so as to pull the plug out when necessary. When doubled on itself it looks like a "comet" in miniature with a nucleus and thirty tails (or twice the number of threads used). A probe, or soft piece of pine but little bigger than a match, is pressed up against the centre, and it is passed back upon the floor of the nasal cavity and pushed on till you reach the posterior nares. This will be known both by the resistance and the length of the probe, or the depth which you have reached. Then slowly withdraw the probe and plug the anterior nares and you have arrested the bleeding. These twenty or thirty ends floating in the blood at once coagulate it. The passage of the soft lint gives no pain whatever. In persuading children to submit to the operation, I often pass the lint up my own nose to satisfy them it gives no pain. If lint is not at hand I use the largest size spool cotton.

Some years ago I called the attention of one of our local societies to this matter, and it was mentioned in a local journal, but attracted no attention. Seeing the notice of Dr. Fridenberg's method in the MEDICAL RECORD, I send this to you hoping it will have a wider circulation. Any sensible layman can perform this operation. Many years ago I was wont sometimes to remain at the patient's house for hours, fearing a return of the bleeding, but do so no longer. The plug is removed in from twenty-four to forty-eight hours. It gives no pain and the patient is willing for it to remain. The other methods are all painful in execution, and the discomfort, while the plug remains, is very considerable.

Progress of Medical Science.

Chemical Alterations of the Gastric Juice in Acute and Chronic Maladies.—The condition of the gastric juice during febrile states has been studied of late by Wolfram. In the acute pyrexias, which included a case of exanthematic typhus, two of intermittent fever, four of typhoid fever, six of pneumonia, the gastric juice, though containing pepsin, showed not the least trace of hydrochloric acid. In several chronic cases, including one of double fibrinous pleurisy lasting two months, and one of phthisis pulmonalis, the gastric juice was normal. Uffelman and others, on the contrary, claim to have seen cases where the fever was not accompanied with absence of hydrochloric acid in the gastric secretion (*The Boston Medical and Surgical Journal*). The alterations in the gastric juice in phthisis have been studied, particularly in Germany, by Hildebrand, Rosenthal, Klemperer, Immermann, and others. According to Hildebrand, the normal acid is wanting when there is continued fever, while it is always present when there is no elevation of temperature. Brieger's observations agree in the main with these results—the acid was wanting in nineteen out of thirty-one cases. At the end of the disease there was present gastritis, with atrophy of the glands. Rosenthal found that, whether in the earlier or later stages, the gastric juice of phthisical patients was generally devoid of free hydrochloric acid. Klemperer distinguishes the initial from the terminal dyspepsia. There is, beside, a pretubercular dyspepsia, in which the secretory activity is normal. In the initial dyspepsia, Klemperer affirms that there is generally hydrochloric hyperacidity. In the final stages he has found the hydrochloric acid deficient or wanting, and the processes of fermentation very much developed. He believes these latter phenomena to be the expression of a subacute or

chronic gastritis. In fifteen cases Einhorn found the natural acid wanting in two cases, intermittent in one, and constant in twelve. According to Shetty there is always hydrochloric acid in the gastric juice in phthisis; sometimes this acid is in excess.

To sum up: It will be seen that there is nothing constant relative to the proportion of hydrochloric acid in the gastric juice of phthisical patients; in febrile cases the acid is generally found wanting; in the afebrile it may exist in the normal quantity or even be in excess. Chelmonsky has in several cases noted absence of hydrochloric acid and diminution of pepsin in emphysema; he has frequently found this acid absent in the course of chronic phthisis. In anæmia and chlorosis, Riegel observed the proportion of hydrochloric acid to be higher than the normal in three carefully studied cases, and Ritter and Hirsch have claimed similar results from their rather incomplete analyses. Hayem, in cases of chlorosis, has found the digestive operations to be sometimes normal, and sometimes profoundly altered; in the latter cases there was deficiency of hydrochloric acid with dilatation of the stomach. In no case did Hayem find hydrochloric excess. Georges has noted hydrochloric deficiency in the anæmic patients whose gastric secretions he has examined, while the organic acids existed in large proportion. In a case of grave anæmia consecutive to hemorrhages, Lyon found absence of hydrochloric acid. In diseases of the heart, according to Hüfler, whether the affection be valvular or muscular, the consecutive circulatory stasis, even when it is little pronounced, suffices to enfeeble or even to destroy the power of the stomach to fabricate acids. Of ten patients, nine had hydrochloric deficiency. Sandberg and Professor Sée have also noticed absence of hydrochloric acid in cardiac affections. According to Einhorn and Ewald the hydrochloric acid only disappears in cardiac patients when there is a catarrhal gastritis. Want of hydrochloric acid in the gastric juice has been found in diabetes, gout, uræmia, progressive pernicious anæmia, and in Addison's disease. According to Bourget and Georges, there is always enough pepsin, or at least of pepsinogenous substance, in the stomach. These writers do not believe in the remedial properties of this ferment when therapeutically administered, and here they indicate a divergence from a considerable clinical experience, which attests to the efficacy of artificial pepsin in many digestive disorders.

The Value of the Injection Test in Doubtful Cases of Ruptured Bladder.—Dr. Walsham writes as follows to *The Lancet*: The value of this test was well illustrated by a case recently under my care at the Metropolitan Hospital. The patient, an elderly woman, had been knocked down and run over by a van, one of the wheels passing over the lower part of her abdomen. On admission she was found to have a fracture of the pelvis, involving the sacro-iliac joint, with considerable separation of the pubic symphysis. She was quite unconscious and in an extremely collapsed condition. The skin was cold and clammy, the pulse small and weak, and the respiration feeble and sighing. When I saw her, shortly after her admission, she was still deeply collapsed, but had slightly recovered consciousness and complained of great pain in the lower part of her abdomen. It was doubtful how much urine she had in her bladder at the time of the accident, since, having only partially regained consciousness, she could not answer this question satisfactorily. I passed a silver male catheter, but only a small quantity of blood-stained fluid escaped, and on depressing the handle the points seemed to be felt more easily than normal by the hand above the pubes. The history of the accident, the collapsed condition of the patient, the fracture of the pelvis, the separation of the pubic symphysis, the pain in the hypogastrium, the escape of only a small quantity of bloody fluid on the passage of the catheter, and the apparent abnormal projection of the point of the catheter above the pubes when the handle was depressed, led me to suspect a rupture of the bladder. Seeing the importance of early recognizing this injury if treatment by suture of the ruptured viscus is to have a fair chance of success, I determined to explore the bladder by an incision above the pubes. Before doing so, however, I thought it as well to try the injection test. I therefore forcibly injected a measured quantity of water into the bladder through a full-sized catheter tightly fitting the urethra, and then after a few minutes drew it off, taking care to prevent any loss. The same amount, within a drachm or so, as that injected was returned. In the face of this test, therefore, I resolved to wait a few hours before undertaking any active measures. Suffice it to say that, in the course of the evening, the patient passed urine naturally. After this she had no further bladder trouble, and made an uninterrupted recovery.

Observations on the Movements of Young Children.—M. Alfred Binet has recently published some interesting observations which he has made with regard to the movements of infants. The first question to which he directed his attention was the way in which they learn to walk. He maintains that the attempts to walk are instinctive, and not the result of education (*The Lancet*). Among other grounds he draws attention to the more or less coordinated treading movements that even an infant of only three weeks will keep up if the soles of its feet are allowed to touch lightly a suitable surface. He believes that the time at which a child learns to walk depends not merely on bodily conditions, such as firmness of the bones, good muscular power, etc., but also on the mental characteristics of each child. Thus he thinks he has established the fact that a child who can give its attention to placing its steps, and whose attention is not easily distracted, learns to walk at an earlier age and in a shorter time than more restless children. He maintains further, that the boy makes the man, and that such children are characterized in later life by the important faculty of close application to work.

M. Binet also directed his observation to the restless movements of young infants, which have been so carefully studied in England by Dr. Francis Warner. He draws special attention to the fact that these movements are almost always bilateral, the two sides being affected either synchronously or alternately. This tendency to bilateral movement is to be noticed not merely in infants, but may also be traced in children of seven years old. If a rubber ball connected with a tambour of a revolving blackened cylinder be placed in each hand of an intelligent child, and he be told at a given moment to squeeze with one hand only, the tracing almost invariably shows that the ball had been also squeezed, although to a much less extent, by the other hand. A similar apparatus was employed to estimate the "reaction time" which elapses between the giving of a signal and the performance of a prearranged movement. A tuning-fork was arranged to mark fractions of a second on the revolving cylinder, and the signal was given by a bell, which marked the cylinder as it was struck. The child then squeezed the ball as quickly as possible. The average "reaction time" with four children, whose ages ranged from three to seven years, was just double that obtained with the same apparatus in the case of healthy adults. The duration of the contraction was also more prolonged, the average in the children being three times as long as that in adults. M. Binet describes with less exactness the very complicated automatic movements which may be excited in an infant by gentle cutaneous stimulation during sleep, and which may not even be noticed by the child when awake if its attention be distracted. M. Binet's observations are opposed to the views of Mill and Bain that our ideas of space, etc., are the result of education, and not intuitive. He says that a child three weeks old, who he is certain had never had a fall, and therefore could not know by experience that it would be attended by pain, will lie contentedly across a person's outstretched arms, if the

hands be placed in such a position as to prevent its slipping down. If, however, the hands and arms be depressed, so that the infant tends to slide down, it will show its fear by at once screaming and struggling. He believes, in addition, that this argues the presence of the muscular sense at this age, in spite of the opposite opinion held by some writers. The same view, grounded on similar observations, was taken by Sir Charles Bell, in his studies of the subject.

The Absorption of Fat.—Minkowski has found that after extirpation of the pancreas animals entirely lost the power of absorbing fat, except in the form of milk, though if pig's pancreas were mixed with the food the fat was digested and retained. He therefore concludes that the secretion of the pancreas is, if not the sole, at any rate an essential factor in the absorption of fat, reducing it to an emulsion, or a state of physical and mechanical division and suspension similar to that in which it exists in milk.

Some Cases of Prolonged Want of Food—Asitia.—Asitia is taken from the Greek word *ἀσιτία*, which expresses want of food, either voluntary or involuntary. A correspondent of *The Lancet* writes as follows on this subject: "The name of General Colletta, author of the 'History of the Kingdom of Naples from 1734 to 1825,' is one of the most respected in the annals of modern Italy, and his reputation for discernment and veracity may fairly be placed on a level with that of the Duke of Wellington in our own country. His description of the terrible earthquake which in 1783 devastated Calabria, and was severely felt throughout the Kingdom of the Two Sicilies is of unquestioned authority, and from it the following incidents are extracted. They refer only to persons and animals imprisoned beneath the ruins caused by the earthquake. It is only necessary to add that the facts were ascertained by General Colletta's personal investigations at the scene of the catastrophe. 1. A female child, eleven years of age, was extricated on the sixth day and lived, and another girl, sixteen years of age, Eloisa Basili, remained underground for eleven days, holding in her arms an infant which had died on the fourth day, so that it was decomposed and putrefied at the time of her rescue. She was unable to free herself from the shocking burden in her arms, so closely were they hemmed in by the fallen wreckage. 2. More wonderful still as regards duration of life were certain cases that occurred among animals. Two she-mules existed under a heap of ruins, the one twenty-two days, the other twenty-three; a fowl lived for twenty-two days, and a pair of hogs, which where completely entombed, remained alive thirty-two days. The human beings who had undergone these unwonted privations, when interrogated as to their sensations, replied, 'I can recollect only up to a certain point, and then I fell asleep.' When it is remembered that all the creatures thus circumstanced were deprived entirely of water or other liquids, it is hardly to be wondered at that though there was no desire for solid food they displayed on their liberation an insatiable thirst, and, the author adds, partial blindness—*sete inestinguibile e quasi cecità*. There is also mentioned the case of an infant at the breast which was disinterred in a dying condition at the end of three days, and then recovered. A pregnant woman lay unassisted for thirty hours beneath a fallen cliff, and some days after her rescue was delivered of a healthy living child."

Septic Peritonitis. — Dr. Bumm, of Würzburg, distinguishes three forms of inflammation of the peritoneum: aseptic, septic, and specific peritonitis (*The British Medical Journal*). The first form is developed through the agency of mechanical or chemical irritation. It generally ends in fibrinous exudation, and adhesions between different abdominal structures are thus established. The septic form of peritonitis includes two distinct varieties, one due to the streptococcus, the other simply putrid. Streptococcus peritonitis is almost invariably the result of puerperal infection. The germs reach the peritoneum, from their origin in the genital canal, either through the Fallopian tubes, or through the uterine walls and surrounding lymphatics. The fluid in the peritoneum, when death occurs very soon after infection is clear and free from odor, but loaded with streptococci and intensely virulent. A mimin, or less, injected into the peritoneum of a rabbit, will rapidly set up deadly peritonitis. The physical symptoms are little marked; the intestines are greatly distended, but their serous coat remains white and smooth, and patches of lymph are few, and pale in color. When death occurs, after the disease has lasted for two or three days, the fluid in the peritoneum becomes puriform and far less deadly to other organisms. The familiar morbid appearances are plainly marked. Streptococci cultivated apart from the fluid developed in peritonitis are also not very deadly. No doubt, men who do not believe in germs will, on that account, contend that it is something which comes with the germs that causes such disastrous results. The germs do the least harm when introduced without any fluid, or when they have dwelt for some hours or days in peritoneal fluid. According to strict scientific evidence, however, it appears that the greatest harm arises from the combination of streptococci with exudation thrown out in the earliest stage of peritonitis. The streptococcus disease, as we may term it, may attack patients, on whom abdominal operations have been performed, through infection, which is probably always derived from a puerperal case. As a rule, however, the disease which follows abdominal sections or perforation of the alimentary canal is "putrid peritonitis." In this variety the exuded fluid is from the first fetid and turbid. It contains, not one specific germ, but a mixture of germs. It does not set up peritonitis if injected into the peritoneal cavity of rabbits in small quantities. In cases of putrid peritonitis the mixed germs lie in a favorable medium and multiply with rapidity. They then are able to set up a widespread decomposition of the fluid in the peritoneum. Hence this disease progresses slowly, going from bad to worse, while the streptococcus variety begins with symptoms of extreme virulence. Of specific forms of peritonitis the tuberculous is the most distinct. According to Dr. Bumm the existence of a gonorrhœal peritonitis is doubtful. Gonorrhœal pus poured out of a ruptured tube into the peritoneum seems to act as an aseptic fluid, provided it be pure, and becomes encysted. When mixed with pyogenic germs the case is different, and septic peritonitis may follow.

The Shuttle-Pulse and Its Portent.—There is a peculiar pulse, says a writer in the St. Louis *Medical and Surgical Journal*, which I have sometimes felt, but never without a shudder, when in the radials of those whom I have loved—never without grave prognostic impression whenever perceived in any patient. I mean the shuttle-pulse, as I would call it; a pulse in which the pulse-wave passes under your finger as if it were floating something solid as well as liquid—that something passes along the blood-current under your finger like the weaver's shuttle through the loom. I have felt it in cases only where the blood was hydræmic and a local rheumatic inflammation existed, or had recently existed within the heart. I have called it the shuttle-pulse, because I can liken it to nothing else, and because the impression it makes suggests that name. If you have ever felt this pulse, did you ever know of a patient recovering after its appearance? Did you ever know a patient, after its appearance, to escape the consequences of embolic closure of vessels? To me it is the pulse of fibrinous coagula going the rounds of the circulation. Its portent has ever been evil. It is a pulse of dark prognosis and painful memories—the pulse of impending death in part or whole. I think I have never known a patient to live after such a pulse had been detected. It is the pulse of fatal rheumatic endocarditis or endoarteritis and its sequent or associate anæmia and emboli.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, October 4, 1890.

THE EDUCATION OF THE SENSES IN MEDICINE.

IT would be a wise measure if medical students had, as a part of their curriculum, systemic courses in the training of the special senses. Some people are born quick and observant, with keen eyes and ready hands; but these are in the minority. Yet everyone can easily train his senses to better work, and it is of vast importance to physicians that this should be done. The eye, the sense of touch, and the muscular or co-ordinating sense especially need training. The student, after glancing over a patient, should be able at once to enumerate every point in physiognomy and physical structure. Trained newspaper reporters will enter a room, and after a minute's inspection can write down all the details of its arrangements. The physician's eye should make a similar report of the body of his patient.

The color of the face, skin, the eyes, the lips, the expression, the posture, the movements, the voice, the breathing, the condition of nutrition, should be taken in at a glance. Practice compels all physicians, if successful, continually to learn to do this, but training for it cannot be begun too early. The sense of touch and pressure needs especially to be cultivated. For this purpose the physician should pay attention to the care of his hands. They should be kept clean, soft, pliable, and should be much protected by gloves. The rough and dirty finger can never be a delicate organ of touch. The *tactus eruditus* can only come after long experience, but less experience will be needed if proper systematic direction is given to the effort. The pulse is an excellent thing upon which to practise. Some surgeons cultivate the use of certain fingers for certain purposes.

Thus Dr. Hachenberg (*Cincinnati Medical News*) recommends:

1. The touch with the tip and inner surface of the end of the right index-finger for the examination of hidden parts, as the os tincæ, rectum, throat, bottom of wounds, etc.

2. The inner surface of the ends of the index- and middle-fingers of the left hand for the examination of external parts of the body—for fluctuations of various kinds, œdema pulsations, to determine the character of early cutaneous eruptions, as in small-pox, etc.

The need of a highly cultivated sense of touch and pressure is very great in external examination of the abdominal walls, and in surgical, obstetrical, and gynecological practice. Dr. Tait says, in his work on "Methods of Diagnosis:"

"It is perfectly impossible for me to convey, by any kind of description, how I can tell by the touch an inflamed vaginal mucous surface from one that is healthy; neither can I describe the feeling that the everted surface of the cervix gives to me which declares the condition of chronic endometritis. But I know that my educated finger-tips can make this distinction. If, on the other hand, I discover a pelvic tumor, long practice enables me to tell with almost perfect certainty, and without the use of the sound, that it is a retroverted fundus or adherent tube or ovary, or by its fading away toward the broad ligament, on one aspect of the uterus or another, that it is an intraperitoneal hæmatocele; while the peculiar resistance of a myoma conveys to my mind an accurate impression which needs no probing the uterus to substantiate. So a cyst reveals itself in a way I cannot communicate. . . .

"Pregnancy, the rock ahead to inexperienced practitioners, can be infallibly revealed by palpation. First of all, there is fluctuation, due to the liquor amnii, and it can be easily detected, and this declares the cystic nature of the mass. If the hand be made to lie gently on the parietes for a few minutes, a rhythmical contraction of the uterus, by which at one time it is hard as a cricket-ball, and at another soft as a cushion, will become perfectly apparent, and this is an infinitely more certain sign than the fœtal head, or the sound of the placental bruit."

The education of the ear is also imperatively required by the physician. Everyone remembers how hard it was at first to hear a cardiac murmur, and distinguish the different râles. The intonations of the voice, and even the fall of the foot, are things full of meaning to the physician.

The olfactory sense is perhaps least of all used in diagnosis, though it is the quickest of all the senses to detect unsanitary conditions, whether external to the body or internal. The nose insists on pure air and cleanliness, and thereby this modest organ has no doubt saved countless lives. The olfactory organs are the most delicate of all the special senses, and perhaps olfaction may in time be more systematically used in the doctor's search after the pathological.

GERMAN SCIENCE AND AMERICAN ART.

THE following comments on German universities and German medicine, from the pen of Professor William Osler, are calculated to inspire a sense of due humility in the American breast. Writing to friends at home, Dr. Osler says (*New York Medical Journal*): "Now, as you are in part a Teuton, it may interest you to know the general impression one gets of the professional work over here. I should say that the characteristic which stands out in bold relief in German scientific life is the paramount importance of knowledge for its own sake. To know certain things thoroughly, and to contribute to an increase in our knowledge of them, seems to satisfy the ambition of many of the best minds. The presence in every medical centre of a class of men devoted to scientific work gives a totally different aspect to professional aspirations. While with us—and in England the young

man may start with an ardent desire to devote his life to science, he is soon dragged into the mill of practice, and at forty years of age the 'guinea stamp' is on all his work. His aspirations and his early years of sacrifice have done him good, but we are the losers and we miss sadly the leaven which such a class would bring into our professional life. We need men like Joseph Leidy and the late John C. Dalton, who, with us yet not of us, can look at problems apart from practice and pecuniary considerations. I have said much in my letters of splendid laboratories and costly institutes, but to stand agape before the magnificent structures which adorn so many university towns of Germany, and to wonder how many millions of marks they cost, and how they ever could be paid for, is the sort of admiration which *Caliban* yielded to *Prospero*. Men will pay dearly for what they prize dearly, and the true homage must be given to the spirit which makes this vast expenditure a necessity. To that *Geist* the entire world to-day stands debtor, as over every department of practical knowledge has it silently brooded, often unrecognized, sometimes when recognized not thanked. The universities of Germany are her chief glory, and the greatest boon she can give to us in the New World is to return our young men infected with the spirit of earnestness and with the love of thoroughness which characterize the work done in them."

We trust that the feelings here expressed may be widely shared, and prove a stimulus to American workers.

It must not be thought, however, that the commercial *Geist* which afflicts our profession is entirely indefensible, or that it is not also very fruitful of good. Americans have been forced by the nature of their environments and the character of their institutions to apply themselves almost entirely to the art of medicine. Every possible method by which disease can be cured or suffering alleviated is ingeniously devised, eagerly appropriated, and its real value quickly determined. We can say, without boasting, that the representative American physician is the best kind of physician—acute, resourceful, kind, sound in judgment, quick in action, patient, never sparing himself.

We have not, it is true, a class of men totally devoted to scientific work and contented with its rewards. But they will come, and some are already here. Of this the eloquent writer of the paragraph we have quoted is an evidence and an example.

THE SALICYLATES IN THE TREATMENT OF PLEURISY.

An esteemed daily contemporary announces to the world that certain Paris physicians have discovered salicylic acid to be a wonderful cure for pleurisy with effusion, and it is kindly advised that American physicians try the drug if "the present epidemic" should continue.

We are pleased to observe the pedagogic interest taken by the daily press in medical matters, but it is highly desirable at the same time that the editorial department be infused with a little more learning before it begins to teach.

The use of salicylate of soda in the treatment of pleurisy was fully described in the columns of the Medical Record over two years ago (August 23, 1888), by Dr. Joseph Drzewiecki. The method of giving the drug and the results are published in detail. Yet the New York *Herald* announces this as a new treatment just promulgated in Paris, and editorially commends it to the attention of American physicians!

The *Herald* sadly needs a competent medical editor, if it is to continue its present department of medical news.

THE METRIC SYSTEM AGAIN.

After some years of quiescence, the metric propaganda is again being taken up, and in a way that promises some results. At a meeting of the American Association for the Advancement of Science, held at Toronto, September, 1889, a committee was appointed to promote the use of the metric system of weights and measures among professional men, and especially among physicians and pharmacists. The committee has issued a very forcible appeal in behalf of the modern system. As a result, in part perhaps, of their labors, the members of the convention for the seventh decennial revision of the United States Pharmacopœa which met in Washington, on May 6, 1890, voted to adopt the metric system exclusively in the next edition of this work.

Pharmacists will therefore be obliged hereafter to make themselves familiar with the grammes, milligrammes, and cubic centimetres.

The arguments in favor of the metric system have often been put forward in these columns, and they are arguments which gather strength each year. It is the system already in use throughout the Continent among physicians, and by all scientists and chemists throughout the world, without regard to their mother-tongue. It is the only system in this country which has been legalized by Congress, and it is in use in the Post-office, Coast Survey, U. S. Navy, and U. S. Marine Hospital Service.

The Committee say: "The argument that our system of weights and measures is the same as that in use in Great Britain, with whom we have most intercourse, is without foundation. The system we use is well called the *American system*, for no other nation uses it. The *Troy* pound has been abolished in Great Britain, and no longer appears in their text books, and the fluid measures are different in the proportion of 4 to 5.

"The actual and intrinsic advantages of the metric system in the arts of medicine and pharmacy are very considerable. The terms used in the old system number at least four, viz., the *grain, scruple, dram*, and *ounce*. To these are really to be added the *minim* and *fluid ounce*. The fluid ounce and the dry ounce are not the same, and the factor of each denomination is different, making four factors to remember and compare each time a prescription is written. If the metric system is used, there is *but one factor*, viz., *the gram*, which is divided according to our ordinary or decimal system of numeration.

"The gram is the essential thought-unit. As the cubic centimetre of water weighs one gram, the units of weight and measure are identical, and only the specific gravity of fluids lighter or heavier than water (of which there are not many used in medicine) need be considered.

"As each sign and factor are separate ideas, there are at least ten distinct thought-elements in the old system against one in the new, and as the chance of error is as the number of terms, the possibility of making a mistake

is ten times greater in the old system than in the metric, given equal practical knowledge of each system in the practitioner.

"Again, the hieroglyphical signs for scruple, dram, and ounce are abolished by the metric system, and the possibility of confusion between the last two vanishes. Also the V and X of the *Roman* numerals give place to the *Arabic* numerals 5 and 10 in common use. The former characters are not infrequently written in such a way as to be easily mistaken for each other, and this source of error, too, is removed by abolishing the use of the Roman characters."

We regret to find the learned advocates of the metric system spelling "gramme" without the final *me*. This may do for scientists and chemists, but the physician should carefully avoid such orthography, for otherwise serious confusion would occur between "gram" and "grain." The average physician is not a model penman, and is not likely to be, and in one case out of every ten in which gram or grain was written, it would be hard to tell surely which word he meant.

In conclusion, the Committee furnishes us with the practical point that an ordinary teaspoon, when full, contains five cubic centimetres, a dessertspoon fifteen, and a tablespoon twenty cubic centimetres.

THE PREVENTION OF SYPHILIS.

In the Section on Hygiene at the recent International Congress, an interesting and important debate took place regarding the matter of licensing houses of prostitution. Dr. Thiry, of Brussels, earnestly advocated the licensing system with sanitary inspections twice a week. Dr. Kaposi, of Vienna, took similar grounds. Dr. Thiry would not allow any prostitute to be licensed under the age of twenty, but Kaposi thought that sixteen was a sufficiently advanced age.

The views advanced by the above gentlemen were opposed by several others, among them Dr. Drysdale, of London, who asserted that, according to his investigations, there was as much syphilis in Paris, where prostitution is regulated, as in London, where it is not.

A vote of the Section was finally taken, and it was shown that a great majority of the members were opposed to regulation.

This is the view which in the present state of society is most in accord with justice, common-sense, and experience. Licensing and sanitary inspection tend to produce secret prostitution; and besides, such methods enforce penalties upon women but not upon men, and are therefore most unjust.

THE RELATION OF BENIGN TO MALIGNANT GROWTHS IN THE LARYNX.

In view of the intense partisanship which has crept into the subject of laryngeal cancer the recent exhaustive monograph by Dr. Felix Semon, upon the question whether benign laryngeal growths ever become malignant, especially after operative interference, will be read with extreme interest.

Dr. Semon's collected material embraces 10,747 cases of benign new growths, observed by 107 laryngologists during the period 1862–88. Of these, 2,531 were cases not operated upon, of which 12 are reported to have undergone malignant degeneration spontaneously; and 8,216 cases in which intralaryngeal operations had been performed, of which 33 cases are reported to have undergone malignant degeneration subsequently to the operation. Of the first series there is 1 case in every 211 cases; in the second series, 1 case in every 249 cases. Hence it follows that, if anything, more benign cases become malignant if left alone than if interfered with surgically. As a matter of fact, however, the conclusion to be arrived at is that benign growths do not become malignant.

This must be pleasant reading to Dr. Morell Mackenzie, who has been bitterly censured, as is well known, for not allowing a radical operation upon the late Emperor Frederick.

The conclusions reached by Dr. Semon as to intralaryngeal growths may very fairly be applied to neoplasms elsewhere.

News of the Week.

The Death of Dr. J. Mathews Duncan took place at Baden Baden on September 1st. Dr. Duncan was born in Scotland in 1826, and has for many years held a leading place among English obstetricians and gynecologists. He made many original contributions to these subjects, the ripest fruit of his work being found in his clinical lectures. The *Lancet* has this to say about him: His style was characteristic; strong and rugged, aiming at clearness rather than elegance, at accuracy rather than effect. This was like the appearance of the man himself. His presence and talk were like the bleak honesty of his native moors. As a physician, patients were sometimes disconcerted by these very qualities, which they did not expect to find in a "ladies' doctor;" but none in trouble failed to find a kind and sympathetic heart beneath his somewhat silent and sententious manner, and he was ever ready to help both with advice and money in time of need. With frivolity and charlatanry he had no patience, and such as possessed these faults found they had met in him with the wrong man. In his relations with patients and his fellow-practitioners self-interest never came in. The interests of the patient were paramount. In appearance Dr. Duncan was of middle height, powerfully built, with an upright, firm carriage. His head was massive; his face was generally impassive, but capable of great expression. His eyes were clear and reflected his moods. His voice, tinged with the accent of his birthplace, was grave and manly. His manner in lecturing was slow, direct, and impressive, and his hearers felt that he was filled with the importance of the subject. He lived in his family, had no clubs, many friends, few great friends, but to such what a great friend he was!

Local Boards of Health of the State of New York.—The New York State Board of Health has just published a complete list of the Local Boards of Health of this State. The book is an evidence of the increasingly thorough sanitary organization which the State Board has brought about.

The Association of American Rhinologists meets at Louisville, October 6, 7, and 8, 1890.

Burials without Death Certificates.—It was lately stated in the British Parliament that fifteen thousand persons are buried annually without any medical certificate of death. The government has promised to inquire into the matter.

The New York Polyclinic has adopted a resolution that only graduates of regular medical colleges, or others legally entitled to practise medicine, shall be admitted as matriculants of the school.

Dr. James A. Lydston, late Chief of the Eye and Ear Department of the Pension Bureau, Washington, D. C., has been called to the chair of chemistry in the College of Physicians and Surgeons, Chicago.

Quarantine at Mobile.—A large number of the citizens of Mobile have petitioned the county authorities to establish at once an adequate quarantine plant for the protection of the city. The estimated cost of such plant is $25,000, and the County Board has replied unfavorably to the request.

American Rhinological Association.—The following papers are announced for the meeting of this Association, to be held in Louisville, on October 6th, 7th, and 8th: "Nasal Reflexes," opened for discussion by Dr. A. B. Thrasher, of Cincinnati, O.; "Tonsillar Hypertrophy, its Influence on Nasal and Aural Inflammation, with Treatment," opened for discussion by Dr. T. H. Stucky, of Louisville, Ky.; "Nasal Cauteries," opened for discussion by Dr. E. R. Lewis, of Indianapolis, Ind.; "Hygiene of the Upper Respiratory Organs," opened for discussion by Dr. L. B. Gillette, of Omaha, Neb.; "Nasal and Pharyngeal Manifestations of Syphilis, Results and Treatment," opened for discussion by Dr. J. G. Carpenter, of Stanford, Ky.; Report of the Insane Asylum Committee appointed at last meeting to make rhinal examinations and report "On the Relation of Rhinal Inflammation to Mind Affection;" "Nasal Hypertrophies," opened for discussion by Dr. John North, of Toledo, O.; "Polypi and other Nasal Growths," opened for discussion by Dr. C. T. McGahan, of Chattanooga, Tenn.; "Administration of Morphine by the Nostrils," by C. H. Von Klein, of Dayton, O.; "Oils in the Treatment of Diseases of the Nasal Passages," by Dr. Edwin C. Painter, of Pittsburg, Pa.; "Removal of Luscka's Tonsil," by Dr. J. Homer Coulter, of Peoria, Ill.; "The Relation of Naso-pharyngeal Disease to Catarrh of the Middle Ear," by Dr. Emmett Walsh, of Grand Rapids, Mich.; "Hay Asthma," opened for discussion by Dr. A. DeVilbiss, of Toledo, O.; "What shall be our Excipients in Nasal Sprays?" opened for discussion by Dr. R. S. Knode, of Omaha, Neb.; "Remarks upon the Subjects read before the American Rhinological Association," by Dr. Thos. F. Rumbold, San Francisco, Cal.

The Medical Society of the Missouri Valley. — At the third annual meeting of this Society, held in Council Bluffs, Ia., on September 17th, and 18th, the following officers were elected for the coming year: *President*, Dr. J. M. Richmond, of St. Joseph, Mo.; *Vice-Presidents*, Dr. B. F. Crummer, of Omaha, Neb., and Dr. G. W. Coit, of Ia.; *Secretary*, Dr. F. S. Thomas, of Council Bluffs, Ia.; *Treasurer*, Dr. T. B. Lacy, of Council Bluffs, Ia. The next meeting will be held in Kansas City, Mo.

Paterson (N. J.) General Hospital.—The corner-stone of the Paterson General Hospital will be laid on Saturday, October 11th, at four o'clock P.M., with appropriate ceremonies. The buildings, which will be of brick and stone, will consist of the administration building, forty by seventy feet, four stories high, with kitchen, laundry, and boiler-house, detached, in the rear. From one end of the administration building a short corridor will lead to the centre of the "ward" building, which is twenty-seven feet wide by two hundred and seventy-five feet long, and three stories high. An elevator in the administration building will serve for every floor. The heating and ventilation is planned after that in use at the Roosevelt Hospital. It employs numerous foul-air ducts, all of which lead to the base of a heated ventilating shaft near the boiler-house. This shaft is twelve feet square and ninety feet high. The iron smoke-stack from the boiler-house, which is two feet in diameter, is placed in the centre of the ventilating shaft and mounts above its top. The capacity of the ward building is eighty-four beds. In addition to this are the many necessary rooms, private rooms, nurses' rooms, etc. The building-site consists of one complete square of ground, entirely surrounded by streets, and is situated in one of the highest parts of the city. The Building Committee consists of fourteen ladies and gentlemen, of which the following physicians form a part: Drs. C. S. Van Riper, E. J. Marsh, W. B. Johnson, Wm. K. Newton, John L. Leal, and Philander A. Harris. John H. Post, of Paterson, is the architect. It is not expected that the work will be completed before the Fall of 1891.

Woman's Medical College and Infirmary. — Dr. George Thomas Jackson has been appointed Professor of Dermatology at the Woman's Medical College of the New York Infirmary.

A Law to Prevent the Introduction of Contagious Diseases from one State to another was enacted by the recent Congress.

The Effort to Boom the Medical College in connection with Johns Hopkins University by making it co-educational goes merrily on. Despatches state that more than sixty thousand dollars have been raised, mainly in Baltimore, Boston, New York, and Philadelphia, and a committee will soon be organized in Chicago. The trustees have not yet said whether or not they will admit women to the hospital school, but the ladies expect their hundred-thousand-dollar offer to overcome all objections.

A Famine Duel.—Jacques, the professional hunger virtuoso of Paris, has sent a challenge to Succi, the famine debauché of Italy, to the following effect: "I, Alexandre Jacques, having been informed that Signor Succi intends attempting a forty-five days' fast in New York, do hereby challenge him once more to fast for endurance under equal conditions. I, the child of France, defy the blatant Italian, Succi. Accept my challenge and starve with me, or be known for evermore as a braggart sailing under false colors.—Alexandre Jacques."

The Journal of the State Medical Society of Arkansas is the title of a new monthly periodical published at Little Rock.

Death from Cocaine.—A young woman has died at Lille from the effects of cocaine injected into her gums by a dentist.

Society Reports.

AMERICAN ORTHOPEDIC ASSOCIATION.

Fourth Annual Meeting, held at Philadelphia, Pa., September 16, 17, and 18, 1890.

The President's Address.—Dr. Willard, after welcoming the members, narrated his experience in the pursuit of orthopedic knowledge in Europe during the past summer. He congratulated American orthopedic surgeons upon their decided and marked superiority as regards the application of general and surgical knowledge, and the benefit to be derived from operative measures in the correction and relief of deformities. The safety, rapidity, and ease with which many bodily defects can be rectified by the knife or chisel, and the great advances made in the practice of antiseptic surgery, are, as a means of relief, more fully appreciated and grasped by American surgeons than by any others. He would, however, give all credit to Macewen for his earnest advocacy of osteotomy, which has been such a marked incentive to workers in all parts of the world; while to Lister belongs properly the honor of securing that advance in surgery which in its varying applications has revolutionized surgical practice.

In regard to mechanical advances, the invention and application of mechanical measures for the correction of deformities, for securing rest, for immobilization, for traction, and for the proper treatment of joint-diseases, Americans can justly claim that they are in the first rank. He then alluded to the Orthopedic Section of the recent International Congress, which was established through American efforts, and which thus, for the first time, gave an official position to orthopedic surgery as a part of the Congress.

The most novel idea associated with this particular branch of work which was shown at the exhibition at Berlin was the ivory joint of Dr. Gluck, of Berlin, by which he proposes to replace excised portions of bone. These joints are intended to remain permanently *in situ*, and maintain the proper functions of the limb. While the subject is as yet only in its experimental stage, both in theory and in practice, he yet deemed it worthy of investigation.

Dr. Beely's apparatus for the correction of deformities of the chest arising from lateral curvature of the spine, by weight-pressure exercised upon the individual in a stooping posture, was highly commended.

Surgical Treatment of Spastic or Cerebral Paralysis in Children.—Dr. Bradford said that orthopedic surgeons had not done full justice to the surgical treatment of this affection, although it is one that occasions distortion and difficulty in locomotion. This is partly because the affection is not a very common one, but chiefly because the disease has been but little understood. Thanks to the neurologist, however, recently light has been thrown upon the nature of the disorder, and it is now readily recognized and its clinical history well understood.

The writer had not been able to gain permanently satisfactory results by the use of mechanical appliances, although in infantile paralysis (sometimes confounded with spastic or cerebral paralysis) appliances are of great assistance, and had not found any assistance from the use of electricity, and but little from massage. Some assistance in light cases had been gained by educating the patients in the use of the muscles, but when the spasm is severe muscular training will prove of little aid.

In affection of the lower extremity from this disorder the writer had had satisfactory results from tenotomy and myotomy of the resistant muscles, *i.e.*, the tendo Achilles, the hamstring muscles, and the prominent adductor muscles, if the latter are involved.

For myotomy the writer preferred an open incision (under antiseptic precautions) rather than subcutaneous division. The limb should be fixed in a corrected (but not over-corrected) position after operation. A light appliance should be worn to aid locomotion for a month or so after operation. Relapses are not to be anticipated after careful myotomy, and in the writer's experience permanent benefit in the patient's locomotion may be expected in children free from mental deficiency. The writer's experience was based on fourteen cases, ranging from four to sixteen years of age. He had had no experience in operating upon adults with this affection.

Tenotomy for Relief of Deformity in Spastic Paralysis.—Dr. Arthur J. Gillette, of St. Paul, reported a case of cerebral hemiplegia in a child, eleven years of age, occurring when the child was twenty-six months old, with resulting talipes equinus, hammer-toes, and flexion at the knee, for which he made a subcutaneous division of the Achilles tendon. The case had been treated without relief by mechanical means during all this time. Simple division of the Achilles tendon permitted the foot to return to the normal position, completely relieving not only the equinus, but the varus and hammer-toes as well, and also the flexion at the knee. Eight months have now elapsed since the operation, and there has been no return of spasm in any of the muscles of the leg. The ankle-joint will permit of almost normal movement, and the patient walks with but a slight limp.

Amputation as an Orthopedic Measure.—Dr. Ap Morgan Vance made a very strong plea for amputation, as often the best and only way to relieve crippling and deformity. Even for convenience sake, especially where the patient is able to command the best artificial appliances, amputation may be wiser than so-called conservative surgery. The orthopedist, from his intimate knowledge of protective apparatus, and its conditions, is a better judge than the ordinary surgeon of the necessity for amputation, as well as where upon the limb it should be made. The difference between a barbarous amputation through the knee-joint, and one three inches above the joint, may be of incalculable benefit to the patient. The orthopedist can frequently relieve, by a proper amputation and the adjustment of a good limb, cases of adult congenital talipes, where painful bursæ have formed; old cases of infantile paralysis (talipes); cases of subluxated knees with anchylosed patellæ, flail-joints, and much shortening, and cases of abominable amputation through the tarsus.

These points, as well as the necessity of the orthopedist bearing constantly in mind, when considering amputations, the limitations and requirements of the artificial limb-maker, were amplified and illustrated by several interesting cases.

A Ready Method of Counter-extension at Knee.—Dr. H. L. Taylor said that the knee is frequently the seat of surgical inflammation, but is favorably situated for diagnosis and treatment. Properly applied counter extension, *i.e.*, in the lines of the degree of flexion instinctively assumed by the patient, with fixation, usually affords prompt relief to the suffering and provides conditions favorable to the nutrition of the joint and the subsidence of the inflammation. Fixation alone, or simple traction, do not give the same results.

The basis of efficient counter extension is the adhesive plasters applied to each side of the leg above and below the knee, and ending in webbing at their ends near the ankle and near the pelvis. To give a firm grasp of the leg I use a pair, or two pairs, of strips of narrow rubber plaster, sewed to the side-plasters near where the webbing is fastened, and wound spirally around the leg toward the knee above and below, that is, I use four three tailed or five-tailed plasters. As an improvised splint we may use two long stiff strips of wood, like laths or window-curtain sticks, cut nearly the length of the leg, and having buckles fastened near each end. They are to be bandaged to the sides of the leg in such a manner that the knee will not be straightened when the webbing is reflected over the ends of the sticks and drawn into the buckles. If there

is much flexion, sticks with the proper angle of flexion can be readily prepared; or, the plasters having been applied as described, a plaster-of-Paris case, with firm edges, in which buckles have been embedded at each side near the ends, may be used as the basis for counter-extension. Whatever the dressing employed, it is of the utmost importance that no prying or twisting force be exerted upon the knee. These simple methods have been used with satisfaction as a temporary dressing in several cases.

Treatment of Infantile Club-Foot Preliminary to Operation.—Dr. F. H. Milliken, of Philadelphia, said that tenotomy and osteotomy are not infrequently performed on infants two and three months old. This is premature practice, and in general is attended by disadvantages, because as they do not walk they do not use their muscles and relapse may occur. If a relapse does occur it is not easily remedied. He would delay all cutting operations until the time that the child might be expected to walk. He advised manipulating the foot from ten to twenty times a day, massage, the faradic current, mechanical means, and plaster of Paris running above the knee.

Sacro-iliac Disease.—Dr. Benjamin Lee said: Inflammation of the sacro-iliac synchondrosis is, in my experience, the rarest of the affections to which the spinal system is liable. Writers speak of it as of quite common occurrence. Sayre in his great work on orthopedic surgery mentions having frequently met it in children. I have never seen a case except in the adult. The only anatomical feature to which I would call attention in prefacing my remarks is the fact that only one-half of the articulation is provided with cartilage, and that the inner or anterior half, viewing the joint vertically.

Then followed the histories of two cases from which the following corollaries were deduced:

1. Disease of the sacro-iliac symphysis induces a characteristic deformity of the spine, of which the features are a lateral displacement of the entire trunk in a direction away from the affected side, a single curve, comprising the entire length of the spine, and the almost complete absence of rotation. 2. It also induces a peculiar rolling or waddling gait. 3. It is often the cause of inveterate and excruciating sciatica. 4. It is useless to attempt to remedy the spinal distortion so long as its cause remains unrelieved. 5. The existence of chronic pain in the sciatic nerve, not yielding in a reasonable space of time to medication, should always lead the practitioner to make a careful examination of the spine and of the region of the ilio-sacral juncture. 6. This affection is more frequently met with in adult than in child life. 7. Its appropriate treatment consists in splinting the pelvis, and thus preventing motion between the opposing surfaces of the symphysis, motion not being its normal function. 8. For the same reason extension cannot be expected to produce the favorable results in this affection that we obtain from it in arthrodial joints. 9. The disease is often of extremely slow development. 10. Its first symptom is abdominal pain, whence it may readily be mistaken for peritonitis, ovaritis, cystitis, and the like. 11. The pain is usually referred to the side on which the injury exists. 12. The existence of severe unilateral abdominal pain, accompanied by little or no febrile action, should lead to the suspicion of the existence of this affection. 13. A mechanic may by a happy chance give temporary relief to a patient suffering from this disease, but as he is entirely ignorant of its seat and nature, he is not perhaps the safest person to refer the patient to.

Persistent Abduction of the Foot, commonly Known as Chronic Sprain of the Ankle.—Dr. Royal Whitman, of New York, said: This is a chronic affection, painful and disabling to the patient; characterized by weakness, stiffness, and insecurity, with a limp when the patient is fatigued. The foot is held in an abducted position, the peronii and extensor longus digitorum being more or less spasmodically contracted, so that the power of abduction is limited or lost. The original cause is usually an injury to the internal lateral ligaments, often resulting in subluxation of the astragalus. Thus the muscular equilibrium of the foot is disturbed, the adductors, working at a disadvantage, become weakened, while the abductors, from increased work, are thrown into a state of spasm.

Treatment.—After etherization forcibly over-correct the deformity and place the foot in plaster bandages in a position of extreme equino-varus. Later, an extended course of massage is necessary, with voluntary exercises by the patient and forced movement by the surgeon, always directed to regaining the range of motion formerly restricted. Later a brace is applied, and the patient re-educated in the proper position and movements of the foot. This affection may be avoided by treating recent severe sprain of this class by immediate rest in a plaster bandage with the foot in an adducted position, followed by a course of massage until all movements are free and painless.

In conclusion, the writer urged the necessity of a more thorough knowledge of the injuries and diseases to which the foot is liable, that patients might be spared the long and useless treatment by liniments and anti-rheumatic remedies to which they are usually subjected.

The Muscular Element in the Etiology of Rotary Lateral Curvature.—Dr. Scudder, of Boston, made a preliminary report of the investigations to establish an index of muscular strength in growing girls for each age from the tenth to the nineteenth year. The report is based on an examination of one thousand and forty-one of the school-girls of Boston. It was conducted by means of a chair especially constructed for the purpose; the muscular strength of the back muscles as a group being measured by a self-registering dynamometer. The results of the investigation show the gradual increase in the strength of the back muscles for the age of the growing child. The importance of this investigation, as establishing a firm scientific basis for a further study of the muscular element in the etiology was shown, as well as its bearing upon the treatment, the prognosis, and the recording of lateral curvature cases.

The Etiology of Scoliosis.—Dr. Lovett said that lateral curvature is an affection that attacks for the most part children under ten years of age. Girls are affected four or five times as commonly as boys, and the patients are, as a rule, below the average in muscular development The very large number of theories which have come before the medical profession show how uncertain is the cause of the affection. A small proportion of cases can be assigned to definite causes, such as empyema, infantile paralysis, cerebral paralysis, and rickets, but the majority must be accounted for by other means.

There are three theories which are in vogue to-day: 1, That unequal muscular action is the cause of the deformity; 2, that unequal bony growth is the primary affection; 3, that superincumbent weight falling obliquely upon the spinal column is the chief factor in causing scoliosis.

It is to the third theory that modern medical opinion tends to incline, inasmuch as it rests on sound anatomical evidence. The other factors undoubtedly enter, to a certain extent, into the causation of very many cases.

Mechanism of Rotation.—Dr. A. B. Judson said that rotation of the spine is a necessary accompaniment of curvature of the spine in disease and also in health. It may be seen in a thin person when the trunk takes a strong curve to the right or left, and is readily observed in the gymnasium. It is one of the normal functions of the spinal column, and adds a sinuous grace to the movements of the trunk. Its cause is found in the fact that when the spine curves laterally the bodies forming the anterior part of the vertebral structure are free to move laterally in the cavity of the chest and abdomen, while the processes forming the posterior part of the column are prevented from the same degree of lateral displace-

ment by being entangled in the parietes, composed of ribs, muscles, and fasciæ.

An important effect of rotation in the deformity produced by lateral curvature is seen in the fact that the curvature is greater in the anterior part of the column than in the posterior. A slight curve in the processes means a considerable curve in the bodies, and an early diagnosis may be made by looking for rotation rather than for curvature.

Rotation may be recognized in a case of incipient lateral curvature by observing scapular obliquity and a prominence of the transverse processes on the side of the convexity. Its effects on the ribs is to produce an inequality in the diagonal diameters of the chest, as detected by palpation between the two hands. In the absence of positive knowledge of the etiology he assumed that lateral curvature is an expression of inability on the part of the muscles (very likely of nervous origin) to hold the spine erect.

He declined to approve of braces applied for the forcible arrest or reduction of curvature. The mechanical difficulties are too great. A knee can be straightened by applying pressure from before backward in the neighborhood of the joint, and counter-pressure from behind forward at points remote from the joint on the long bony levers which compose this joint, but he would not try to straighten by pressure an upright column of a score of short bones thrown into a double or triple curvature with the added complication of rotation at two or three points in opposite directions.

He would advise the patient to avoid fatigue from whatever cause, and to assume for as many hours in the twenty-four as is practicable those attitudes in which there is the nearest possible approach to symmetry. In this way the increment which belongs to the growing child will be on the right side of the line between symmetry and deformity. The patient should sleep supine, with lordosis produced by an air-pillow. The same position should be taken a portion of every day. Suspension should also be practised up to, but not beyond, the point of fatigue.

Treatment of Lateral Curvature.—Dr. Bradford said that the study of lateral curvature has reached a new stage. More thorough methods of investigation have thrown doubts upon the former theories of etiology and pathology of this deformity, and to-day we are in search more critically for the truth in this surgical riddle. We may assume that the affection is in some way the result of superincumbent weight falling irregularly, owing to faulty attitudes, upon a spinal column, with an imperfectly resistant osseous structure, as is seen in adolescent knock-knee.

For convenience in treatment it is well to group the cases met in four classes: 1, Non-resistant curves; 2, slightly resistant curves; 3, severely resistant curves; 4, rigid curves.

It will be admitted that the affection is a self-limited one, and the distortion becomes in time arrested, and this arrest of increase may be observed as having taken place in each of the classes mentioned. Although this is doubtful as to the first class, it will never be safe to consider that an arrest has been established until some time after growth has been completed.

Treatment necessarily varies according to the class of the case. In the first class the treatment should be gymnastic or postural (Roth's method) according as the curve appears to be due to muscular weakness (determined by Scudder's method), or from habit. The chairs to be used, the hours of study, the amount of recumbency, and general hygienic measures, all need regulation. In this class of case a permanent cure can be expected if persistent care is used. In Class 2 the same measures are needed, supplemented by methods for forcible correction of the curve, such as has recently been recommended by Lorenz and others. This is also true to a greater degree in Class 3. The writer advised, in cases of this class, when from the probability of rapid growth or weak condition an increase of the curve was dreaded, to use for a time stiff corsets for the purpose of insuring avoidance of faulty attitudes as far as is practicable.

The writer has used leather corsets made from plaster jackets, but he has also recently tried plaster jackets applied to the patient, on whom lateral pressure as well as suspension is applied, though at present he is unable to give a definite opinion as to results.

In Class 2 a cure may be expected with an improvement of the curve. In cases of Class 3, prevention of an increase of the curve is all that can be expected. In cases of Class 4 the writer found no satisfactory results from treatment, other than the relief of symptoms of pain, by gymnastics and in some instances a corset.

The Treatment of Lateral Curvature.—Dr. Henry Ling Taylor said that in the absence of a scientifically observed and properly digested clinical history, and a satisfactory theory of pathology, there is no complete basis for a thoroughly rational treatment of lateral curvature. We must bear in mind that some cases have been arrested in the milder stage without treatment; others, however, and probably the majority of those brought to the surgeon, have a decided tendency to grow worse. In the milder stages of the affection, general and special hygienic and tonic measures should be adopted, and all the mental and bodily activities adjusted with a view to eliminating deleterious influences and invigorating the system. There is an undue proportion of the over-taxed, precocious, and intense type among these children, and careful investigation will often reveal mental, emotional, or physical over-strain in some direction. In general the school work will need regulation as to manner or quantity; piano practice should be reduced to a minimum or abolished, and anything that tends to pervert the storage of force or to disturb the equilibrium of the nervous system should be corrected. Habits of regularity in eating, exercise, and sleeping should be introduced, and moderate exercise, with stated rests in the daytime and plenty of fresh air should be insisted upon. The particular indications vary in the individual cases, but when seen early these measures are usually successful. If our recorded observations show that the patient is growing worse, we use, in addition, carefully regulated special exercises, some of them passive and given by means of apparatus driven by steam-power. These favor correction of the deformity, increase of flexibility in the stiffened regions of the spine, and improvement of circulation and nutrition, muscular tone, and general vigor. By these means we nearly always succeed in improving the general health, and frequently the carriage and figure of the patient, by the increased tone and buoyancy of the system. While active and postural exercises are undoubtedly beneficial, if used with judgment, we should avoid taxing the patient by a too strenuous insistance on them.

In many instances, in addition to these measures, the back will require mechanical support, which we furnish by an apparatus on the principle of lateral leverage, and adapt to the requirements of the case in hand, but only when the co-operation of the patient enables us to carry the case progressively forward by frequent manipulations of the apparatus to produce certain definite results; and thus, in properly selected cases, mechanical support has been a great aid.

A Report of Sixty-two Cases of Hip Disease, Observed in the Practice of Hugh Owen Thomas.—Dr. Ridlon reported on 62 cases of hip disease which he had personally examined and measured. Four were new cases, and were recorded simply to show the condition of cases when presenting for treatment. The average duration of limp in these cases before treatment was commenced was a little over ten months. The average duration of treatment was not computed, as only a few were cured cases, and as many had been under treatment but a very short time.

Of the 58 cases that had been under treatment for a longer or shorter time, 24 had shortening from one-quar-

ter to two and one-half inches; 24 had adduction; 5 had abduction; 3 had inward rotation; 2 had outward rotation; and 1 had in-knee. At some time during the course of their disease 24 had one or more abscesses. In 31 cases motion was not tested least it should harm the patient. In 27 it was tested; 12 had no motion; 10 had some motion; 2 had motion to ninety degrees; and 3 had normal motion. In all the cases the general health was good.

In conclusion the following suggestions were offered: In very many of the cases where the joints had been only partially immobilized (by the use of the short splint), and where there had been no protection from the superincumbent weight and the concussion of walking, the results were imperfect; but in those cases where the long splint had been worn until a cure had been effected, and where the horizontal position had been maintained until all pain and muscular spasm had subsided, and where crutches and a high patten had been employed, a cure had been effected without flexion or other deformity than the shortening due to actual bone erosion and arrested growth. Motion at the joint, in the cured cases, was found in a large proportion of cases as compared with the results of other plans of treatment.

Lateral Deviation of the Spine in Pott's Disease.—Dr. Lovett said that lateral deviation of the spine appeared to be a universal accompaniment of early Pott's disease in the lumbar and dorsal regions, and that it was a symptom of much diagnostic significance. The trunk is seen to lean to one side or the other and the distortion is much more prominent when seen in front than behind. This lateral distortion is accompanied with a certain amount of rotation of the spine on a vertical axis, but this does not occur so uniformly or follow the same rules as in true scoliosis.

In thirty consecutive cases of all grades of Pott's disease, recently measured, all but one showed lateral deviation from two to eight degrees. The deformity was least in cases under efficient treatment by braces or jackets. The deviation in most cases does not appear to be caused so much by unequal wearing away of the vertebral bodies, as to be a symptom due to irritation and muscular spasm, being analogous to the malpositions noted in hip-disease and tumor albus. The symptom improves rapidly under treatment, and although improving under any efficient treatment directed to the Pott's disease, it disappears most rapidly if the patients are treated by recumbency and spinal extension.

The Diseases of the Eye Associated with Caries of the Vertebræ.—Dr. Young in his paper pointed out the fact that the disease of the eye and the caries of the vertebræ are of the same pathological nature, strumous or tubercular, and have the same etiology, namely, insufficient diet and infection. He considers the majority of cases of spondylitis as tubercular; and stated that in scrofulous persons there is a constitutional predisposition to caseation or a tuberculosis of irritated parts, the scrofulosis, when the bacillus tuberculosis has actually infected the diseased area, being succeeded by tuberculosis.

The paper concluded with the following summary: 1. The diseases of the eye associated with caries of the vertebræ are scrofulous or tubercular, the difference being principally in degree. 2. Scrofulosis may be considered as the constitutional predisposition to caseation; tuberculosis as the same condition infected with the bacillus tuberculosis. 3. Both the lesions of the eyes and the caries of the vertebræ yield most readily to combined constitutional and local treatment.

Posterior Rachitic Curvature of the Spine.—Dr. Ketch said of the deformities of the spine whose underlying cause is found in the condition known as rachitis, the ones most commonly seen in practice are the lateral and posterior. The etiology and pathology of posterior rachitic curvature of the spine are essentially those of rickets in general, the deformity being simply one of the local manifestations of a general diathesis. Dr. Ketch believes the causation is largely mechanical, and furthered by such movements as tend to throw the weight of the body on the weakened vertebræ and its appendages. Rachitis of the vertebræ evinces itself, as does rachitis, usually at a very early period of life, by an irregularity in the process of ossification, by cartilagenous enlargements, and by marked diminution of the harder substances entering into the bony formation, notably the lime salts. In consequence of this unstable condition of the rachitic vertebræ, we find in the long axis of the spinal column many soft places, in some cases including the upper and lower surfaces of all the vertebræ, in others localized to a few.

A large number of cases show a limitation of the curve to the dorso-lumbar spine, a very favorite position for the occurrence of Pott's disease. In addition to the deformity we may have more or less pain, spinal rigidity, pseudo-paralysis, or any of the distinctive symptoms relating to the area of disease. He then called special attention to the differential diagnosis between this deformity and spinal caries.

In the treatment of young children from one to two years of age, he never advises the use of mechanical supports, the tissues being so unstable that any pressure is apt to be badly tolerated. In this class the constant recumbent position, with fresh air and sun-baths, together with internal treatment and close attention to the diet, are usually sufficient. In older cases, after the acute stage has passed, he advises antero-posterior support.

Relief of Paraplegia.—Dr. A. J. Steele, of St. Louis, said that cases of paraplegia, especially those resulting from acute polio-myelitis anterior, have been, by the employment of apparatus, placed on their feet so that with the aid of crutches they can get about well and comfortably. Massage and electricity find place, also division of the contracted tendons and tissues that prevent straight positioning of the limb. Then, over gypsum casts of the trunk, the thighs, and the legs, leather corset and encasing splints, accurately fitting and lacing in the front, are made. These and the shoes are connected together by riveting steel side-pieces jointed at the ankles, knees, and hips. Stop-joints are placed at the ankles to prevent falling of the feet beyond a right angle, also at the knees to prevent hyperextension, and lock-joints at the knees, by large ring, to allow of sitting; also at the hips when there is marked flexion. Strong webbing is placed back of the hip-joints, connecting the corset with the thigh-pieces, a substitute for the paralyzed extensors. Knee-caps may be necessary to overcome flexion at the knees. With the body thus encased the upright position and, after some education in the use of crutches, locomotion becomes possible.

The Prognosis of Pressure Paralysis.—Dr. T. Halsted Myers said: In 1,570 cases of Pott's disease presenting at the New York Orthopedic Dispensary, 218 were known sooner or later to have become paraplegic. Estimating the duration as to the period from the onset of any symptoms until the patient could walk well, the average duration of those paralyses whose duration was known was, in the cervical region twelve months, in the dorsal region above the eighth vertebra nine and one-half, in the lower dorsal six, in the lumbar eight months. This average period was less where the paralysis came on during treatment, as it did in 85 cases, viz., cervical five, upper dorsal seven, lower dorsal five, lumbar three months.

Neither the character of the kyphosis, the presence of abscess, the rapidity of onset, the duration of disease before onset of paralysis, nor the number of preceding attacks seemed to influence the prognosis. Paralysis of the bladder, lasting two months in several cases, and in two cases three and four months, was entirely recovered from.

Of all the paralyses whose termination was known, 115 in number, all but 4 or 5 recovered completely. These died of intercurrent diseases.

Election of Officers.—The following officers were

elected for the ensuing year: *President*, A. B. Judson, M.D.; *Vice-Presidents*, Ap Morgan Vance, M.D., and George W. Ryan, M.D.; *Corresponding Secretary*, Samuel Ketch, M.D.; *Recording Secretary and Treasurer*, John Ridlon, M.D.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, September 22, 1890.

A. S. HUNTER, M.D., PRESIDENT, IN THE CHAIR.

Initiation Fee.—DR. C. H. AVERY, Secretary of the Society, withdrew his previous motion to reduce the initiation fee from five dollars to one dollar, in favor of an amendment to the By-laws recommended by the Comitia Minora to reduce this fee to two dollars, action to be taken thereon at the annual meeting. The Comitia also recommend that the editor of the Medical Directory be *ex officio* a member of the Comitia Minora.

Nominations.—For *President*, Andrew F. Currier, O. B. Douglas, J. L. Corning, H. T. Hanks (declined), and A. S. Hunter (declined); *Vice-President*, J. L. Corning, A. M. Jacobus, W. E. Bullard (declined); *Secretary*, Charles H. Avery; *Assistant-Secretary*, W. E. Bullard; *Treasurer*, John S. Warren; *Censors* (five to be elected), Daniel Lewis (declined), George E. Abbott, William McLaury, A. S. Hunter, R. Van Santvoord, E. A. Maxwell, Laurence Johnson (declined), G. T. Jackson, S. O. Vander Poel, N. G. McMaster, W. C. Jarvis, W. Washburne, C. F. Milne, G. F. Carey.

The Diagnosis and Treatment of Certain Abdominal Diseases Principally Characterized by Symptoms of Peritonitis.—DR. H. T. HANKS read the paper. A pretty broad field was covered in comparatively few words. Speaking of diagnosis, the author said that when symptoms of peritonitis were present the condition of all the abdominal organs should be interrogated before the conclusion was reached that it was idiopathic. It was strange what a change had taken place in our ideas about idiopathic peritonitis. Dr. William H. Draper had recently told him that on looking back over his experience he now recognized that few of the cases which he had once supposed were cases of idiopathic peritonitis were such in fact. Dr. Hanks had had but three or four cases, and in those it could not be positively said that the peritonitis was not secondary. In the past we had based the diagnosis of peritonitis on such symptoms as pain in the abdomen, tympanites, rapid pulse, pinched face, etc., symptoms which to-day we knew might be produced by hepatitis, perihepatitis, metritis, acute congestion of the kidneys, gastritis, etc.

The necessity for an accurate diagnosis became evident when the question of treatment arose. Should we go on giving large doses of opium in the treatment of cases which formerly were looked upon as peritonitis, but which under improved methods were now recognized as fecal impaction, appendicitis, pyosalpinx, etc.? The author related some cases, among them two of ovarian cysts with twisted pedicles, in which only an operative procedure could have saved the patient.

Keep the Bowels Open.—The author believed that when peritonitis existed or was threatened the bowels should be kept open by salines or enemata. An anodyne should be administered simply to procure comfort, and codeia was preferable to opium because of the constipating effects of the latter. If the fever was high the ice-coil should be applied. Probably the most common cause of general peritonitis was infection extending from the tubes or exposure and imprudence during ovulation. Appendicitis was another common cause. Wherever pus existed one should operate; where it had not formed, seek to make the patient comfortable, give codeia, use salines to keep the bowels open, apply leeches, hot douches in the rectum and vagina three or four times a day. Any case not profoundly septic would probably improve under such treatment. The author had operated for inflammation of the vermiform appendix three times, with one death; had treated ten other cases, suppuration taking place in but one. If under the local treatment suggested for these cases the symptoms gradually grew worse, especially if the pulse became more and more rapid, the face more and more anxious, the pain more and more severe, even though the temperature did not run high, the laparotomist should be summoned. Some had advised an operation even before pus had formed. The mortality from the operation had been great.

Peritonitis in Children.—DR. A. JACOBI was requested to open the discussion, and, at the suggestion of the author of the paper, made some remarks on peritonitis in children. He said that pathologically and anatomically it was the same in infants as in adults; the causes were about the same, except a large number of cases in the adult originated from pelvic tumors. He agreed with the author that in nearly all cases peritonitis was secondary, in many cases the diagnosis of this disease was erroneous, yet in many more instances its presence was overlooked. Many cases of so-called belly-ache were due to peritonitis, sometimes acute, oftener subacute, but most frequently exacerbations of chronic peritonitis. A typhoid ulcer might leave a spot where perforation would take place twenty years after typhoid fever. Agglutinations between the intestines, found where not expected, meant old peritoneal inflammation. Such patients complained at times of abdominal pains. Perityphlitis was common in children, exacerbations occurred and, perhaps, compelled them to go from school to their homes, where they might get a whipping for having the belly ache or be so sick as to compel the attendance of a doctor. Children with abdominal pains due to recurrent peritonitis should always wear a tight bandage to keep the bowels from jolting.

Opium or Laxatives?—Dr. Alonzo Clark, he said, was one of our great men. He instituted the opium treatment of peritonitis in severe acute cases. Laxatives had been given very early before his time, but with the opium treatment patients were found to do better, and it was concluded that, as a general thing, purgatives in peritonitis would not do good; that they were apt to do harm, always excepting cases the result of fecal impaction, where the bowel must first be emptied and rest secured afterward. If, then, the opium treatment proved best in Dr. Clark's hands, and the laxative treatment proved best in Dr. Hanks's hands, it certainly behooved us to find out in what cases the one treatment was demanded, and in what ones the other, or whether purgatives were called for in the beginning and rest afterward. Where peritonitis had existed more than a day or a day and a half adhesions would have formed, and a purgative would cause them to break and give rise to hemorrhage and renewed inflammation. The speaker was sometimes unable to say at the bedside whether a purgative or opium was called for, but when the latter it should be given in sufficient amount to cause sleep for at least twenty-four hours.

Peritonitis in Bright's Disease.—DR. WILLIAM H. THOMPSON said he would speak of two facts only. The first was the frequent presence of purulent peritonitis found post mortem in cases of Bright's disease, which had, perhaps, not even been suspected during life. He always looked for it in the terminal stage of Bright's disease when there was a small, rapid, incompressible pulse, the incompressibility differing from that peculiar to the kidney disease itself. The temperature might not be increased in the least.

The other point was the absence in many instances of pain or rise of temperature from intestinal perforation in typhoid fever. If anything could be done here it rested with the surgeon.

Cirrhosis of the Liver and Peritonitis.—Dr. Thompson corroborated Dr. Jacobi's remarks on the frequency of peritonitis, and said it was usually present all over the

abdomen in cirrhosis of the liver, and was more often the cause of abdominal pains in alcoholics than was gastritis or gastro-duodenitis.

A Sudden Pain Diagnostic.—He said there was a diagnostic point connected with a sudden pain, as distinguished from a slowly developing pain in general peritonitis. It indicates perforation of the hollow viscera.

Three Classes of Cases.—Dr. C. C. Lee divided the cases of peritonitis from the view of treatment into three classes. The first comprised those of a septic nature, following laparotomy, many of which formerly died, but now often recovered under the only proper treatment, namely, operation. The symptoms of peritonitis here simulated a malarial condition. There was less pain than in other cases. The second class included acute cases, which might be called traumatic. Here the question of opium or cathartics arose. He thought abdominal surgeons were in error in leading physicians to think that salines would cure all these cases. They removed only one of the complications of the peritonitis, namely, fecal accumulations or gases. He would begin the treatment of such a case by a saline cathartic, and then seek to keep the bowel quiet. Nothing was better for this purpose than opium unless it was codeia. As to the ice coil, it was useful only in the formative stage; as soon as the stage of plastic deposit had arrived it would do harm rather than good.

In secondary peritonitis, successful treatment depended on removing the cause. It was more a question of when not to operate than when to operate. He thought we would return to a lesser amount of abdominal surgery than is being practised to-day.

Puerperal Peritonitis.—Dr. Egbert H. Grandin limited his remarks to puerperal cases. In the early part of his professional career he began at once, when he met with a case of peritonitis, to dose the patient with opium, and she died. Of late years he had altered his therapeutic methods to a considerable extent. He saw fewer cases of puerperal peritonitis since cleanliness had become almost universal, yet, when a case did arise, he began treatment with salines, and continued their use and avoided opium as far as possible. They brought about a derivative effect, also prevented adhesions, and led the patient to recovery. The vagina and uterus should be kept clean. If there was rupture of a pyosalpinx or ovarian abscess, laparotomy would be called for.

Opium too long Continued.—Dr. Ralph Waldo said he had had occasion to see patients who had been treated successfully for repeated attacks of acute peritonitis by opiates, but the narcotic had been continued longer than necessary, the patient calling for it on account of her hyperæsthetic state, and the result was such complications as impaction of fæces and digestive derangements.

Severe Peritonitis Fatal.—Dr. R. A. Murray emphasized the fact that primary peritonitis seldom occurred, and said that in really severe peritonitis all remedies almost always failed. Puerperal peritonitis was most often seen by the general practitioner, and treatment by either opium or laxatives was likely to fail, simply for the reason that the cause, infection, was not removed. Keep the uterus clean, as one would keep the abdomen clean after laparotomy. In peritonitis after operations, salines removed serum and the nidus for the development of germs; follow them by opiates to secure rest; if there was shock, give large doses. Modern treatment by opium was very different, he said, from what Dr. Clark had meant, which was to administer it in large amount where there was shock and prostration of the nervous system. It acted as a powerful heart stimulant. If there was sepsis the source of infection must be removed.

Hot Claret is said to be an excellent gargle in acute sore throat, being an agreeable astringent and non-poisonous.—*College and Clinical Record.*

OUR LONDON LETTER.

(From our Special Correspondent.)

AUTUMN CONGRESSES—THE SANITARY INSTITUTE CONGRESS—NATIONAL LOSSES THROUGH SICKNESS—THE LIVING EARTH AS A SANITARY AGENT—THE BRITISH DENTAL ASSOCIATION—FASHION IN REMEDIES—DEATH OF DR. MATHEWS DUNCAN.

London September 5, 1890.

The autumn is generally the season of congresses, and among those just held or now in progress are the following: The Sanitary Institute Congress, the Annual Meeting of British Association for the Advancement of Science, the Annual Meeting of the British Dental Association, and the British Pharmaceutical Conference. Sir Thomas Crawford was the President of the first-named of these gatherings. In his address he pointed out anew the important amount of labor lost to the nation through sickness on the part of the workers. He illustrated his remarks by statistics drawn from the records of the Army Medical Department. As the former chief of the Department Sir Thomas Crawford was naturally completely at home in this field. He showed that, adding to the actual sick leave the probable duration of the non-effectiveness of men invalided, the average sick time would be about twenty days per man per annum. There were no trustworthy statistics of sickness among civilians, though, from the various data available, Sir James Paget had maintained that the loss from sickness between the ages of fifteen and sixty-five in England and Wales amounted to twenty million weeks' work per annum, or one-fortieth of the work done in the year by the whole population within the limits of age stated.

In the section of Sanitary Science, the President (Dr. Vivian Poore) gave an address on "The Living Earth." We had, he said, arrived of late years at a certain knowledge of the fact that the mould which formed the upper stratum of the ground we lived on was teeming with life, animal and vegetable. Saprophytes and their allies abounded everywhere. These micro-organisms were very active in producing changes in organic matter added to the soil—changes usually in the direction of oxidation. If the soil were sterilized, by heat or otherwise, it was no longer capable of producing any chemical change in organic matter. The vegetable living mould on the surface was a filter of the most perfect kind. Some of the bacteria in the soil might be hurtful to mankind, but, as a general rule, the great doctrine of the survival of the fittest held good for them. Organisms that flourished in the human body languished and ceased to multiply in the soil where conditions were unsuitable for their multiplication, or even for their survival. In our sanitary arrangements we had not sufficiently distinguished between the living mould and the dead earth of the subsoil. When we perforated the living humus with a pipe and took our dirty water to the subsoil we, as it were, pricked a hole in our filter. Sanitation was purely an agricultural question, and in the country, where every cottage had, or ought to have, its patch of garden, there ought to be no difficulty in the daily removal of refuse from the house, and in applying it to agricultural purposes without any risk of contaminating the water-supply. Sanitation by water had for its main characteristic incompleteness, and Dr. Poore argued at some length in favor of the earth system.

Dr. Rentoul's scheme for a public medical service has not found much favor with the medical profession. At the annual meeting of the British Dental Association, however, the Honorary Secretary (Mr. Morton Smale) said the Council had been considering how dentists could join in the scheme and provide the industrial classes with good professional attendance at a moderate cost. Mr. Browne-Mason, in his presidential address, urged the ap-

pointment of dentists in military and in naval hospitals and at naval stations.

At the British Pharmaceutical Conference, the President, Mr. Charles Umney, spoke at some length in his presidential address on the subject of fashion in medicine. He decried the practice of discarding antiquated —though well tried—remedies in favor of newly introduced ones. The fashion of prescribing medicines in the most concentrated form in which the ingredients were compatible was a dangerous one to the public, owing to their inability to measure small doses exactly. Mr. Umney laid great stress on the subject of the injudicious selection by the public of household medicines. All patent medicines were not useless or dangerous, but he could not remain oblivious to the fact that a section of the public became habituated to the use of narcotics solely from the cloak adroitly spread around the matter by the patent-medicine regulation. I must defer till my next letter some notes on some topics of medical interest discussed at the British Association Meeting at Leeds.

By the sudden death of Dr. Mathews Duncan at Baden-Baden, a few days since, British obstetric medicine loses one of its foremost exponents. Born in Aberdeen, sixty-four years ago, Dr. Mathews Duncan graduated at the university in that city and soon began to work specially at obstetrics, and his original work in various departments of obstetric science gained him considerable renown. His reputation was not confined to the north of the Tweed, for about a dozen years since he was invited to come to London to accept the post of Obstetric Physician to St. Bartholomew's Hospital, an invitation which he accepted. Dr. Duncan's advent to London followed shortly upon that of Sir Joseph Lister (then Mr. Lister) who similarly came south by special invitation. A rather ill-natured rumor was circulated at the time concerning the manner of his coming. In issuing an invitation to Mr. Lister to come to London and accept the post of full surgeon to King's College Hospital some members of the medical and obstetric staff of that hospital were, it was said, specially active. It was hinted that metropolitan hospital surgeons were by no means anxious to have such a distinguished northern surgeon as Mr. Lister brought to London as a rival, and that they revenged themselves on the obstetricians by promoting Dr. Duncan's candidature at St. Bartholomew's Hospital. Be this as it may, a probably important factor in determining Dr. Duncan to come south was his failure to secure the chair of midwifery at the University of Edinburgh. He was then an extra-academical teacher at Edinburgh and became a candidate for the professorial chair on its becoming vacant. He was without question the most distinguished candidate in the field, but the professorship was bestowed on Dr. Russell Simpson, a relative of the late Sir James Y. Simpson. On coming to London, Dr. Duncan speedily gained a position as a teacher and practitioner. St. Bartholomew's is the largest of the metropolitan medical schools and Dr. Duncan soon impressed those around him with a sense of his individuality. He was a man in whom patients felt confidence and soon acquired a large consulting practice. In 1880 he became an examiner in obstetric medicine at the University of London. In this capacity Dr. Duncan perhaps shone least; at any rate, he was by no means a favorite with candidates. In 1883 he delivered a course of lectures on "Sterility" at the College of Physicians. He wrote papers also from time to time, but most of his original work was done in Scotland in earlier years. By that he will be chiefly remembered. Though not without his crotchets, even those differing from him could not but acknowledge that Dr. Duncan was a master in his own department, and his death is undoubtedly a loss to medical science.

The Asheville Medical Review is the name of a new medical monthly at Asheville, N. C., and edited by Drs. F. T. Meriwether and H. Longstreet Taylor.

HYDROPHOBIA BEFORE AND AFTER PASTEUR.

To the Editor of the Medical Record.

Sir: In your number of September 13th I saw an editorial entitled "Hydrophobia Before and After Pasteur," which to some extent concerns the New York Pasteur Institute. For this reason I take the liberty of appealing to your courtesy and to your sentiments of medical confraternity, and of begging you to allow the Director of this Institute to answer this article by showing, as well as possible, the present position of the question of the preventive treatment of rabies. Indeed it is an important question from the stand point of human life and of the frightful anxiety that may be undergone by an all too large number of unfortunate victims. Moreover, you are certainly led by sentiments too lofty to set aside anything that may serve to enlighten the profession upon the matter, and to establish the facts under their true light.

The article in question asserts that "rabies increases *pari passu* with the erection of institutes intended to prevent it." I am led to wonder upon what documents such an allegation is based. I know that the authority of Professor Peter, the declared enemy of all new theories, is advanced. But this authority loses considerable weight if we consider that Dr. Peter is by no means an experimenter, and that he still denies the influence of microscopic organisms upon the production of infectious diseases.

However, as I am not willing to concede that my brethren possess a tendency to knowingly alter facts, I shall admit at once that cases of bites by rabid dogs have more frequently been recorded in America (as elsewhere) since the opening of the Pasteur Institute. This fact admits of most easy explanation; people that had been bitten have come for treatment from Nebraska, from Louisiana, from Arkansas, from Arizona, from Texas, from several of the Eastern States, from Canada, etc., generally under advice of their physicians. Am I wrong in asserting that no one in New York would ever have heard of these cases if they had not come to New York for treatment? Thus does "rabies increase *pari passu* with the erection of institutes founded for the purpose of preventing it."

I will not stop to refute the statement that people who die of rabies die of fear only. This is rather too childish; in that case the animals who die of rabies after inoculation of saliva, or, better, of the nervous substance of such patients, also become afflicted with an imaginary ailment!

"*Alors, à quoi bon, Pasteur,*" if the partisans themselves of his method demand police regulations to cope with an increase of cases? Such is the question asked by the Medical Record, after Peter. This can scarcely be allowed as a reasonable objection. Can Pasteur be responsible for recrudescences that may occur in canine hydrophobia? Moreover, one might as well say, Wherefore your vaccinations since your boards of health take such stringent measures against the spread of small-pox?

Then I must state that before Pasteur's discovery many people who had been bitten submitted themselves more or less stoically to their fate. Nowadays, knowing that a preventive method against rabies exists, once bitten, people are informed of it, and the patients go and seek treatment. If it is shown that the biting animal was rabific, or reasonably suspected of being so, they are treated; if not, they are reassured and sent away. Among six hundred people who presented themselves at the New York Institute during seven months, a hundred and twenty were kept, and that for the whole of the United States. I will add that not one of the people who have been treated is dead, whereas, to my knowledge, about a dozen deaths caused by rabies have occurred during the same space of time in people who were not treated. In two cases, moreover, the same dogs who had caused a

fatal termination in other persons had also bitten people who were treated and are well.

It is insinuated that "preventive inoculations are capable of giving rabies." To this insinuation facts answer, most emphatically, no. Here is the reason:

1. Among ten thousand people who were inoculated in Paris, about fifty—or about one in two hundred—have died, notwithstanding the treatment (either having applied too late for inoculation, or for other causes). If these persons had died by reason of the preventive inoculations, the intracranial insertions that were performed on rabbits with the bulbar matter of these patients would have killed the animals in a period of from nine to eleven days, as always occurs when the powerful virus employed at the end of the treatment is used. On the contrary, it was not until eighteen to twenty days that death supervened in the animals that were experimented on, just as happens when they are inoculated with virus taken from the common mad dog. These people, therefore, were not killed by the virus of injection, but by that of the animals that had bitten them.

2. Another proof that Pasteur's inoculated patients did not die of the treatment lies in the instance of the five people who died after the injections that were performed by Dr. Bareggi, of Milan, *after the method of Ferran* (extra virulent inoculations performed *ab initio*), and not after Pasteur's method. These people presented an altogether different set of symptoms (light headaches, vomiting, progressive paralysis of the lower extremities with fever, without salivation or sensorial irritation, nor had they difficulty in drinking, nor photophobia, nor delirium, nor convulsions).

As to the efficacy of the treatment—now that I have shown its innocuity—I feel nearly puzzled as to how to go to work about defending it, so much does it appear as a commonplace to speak to-day of the true and marvellous results that have been acquired and observed by all who have taken the trouble so see and find out for themselves.

At present the physician has somewhat left behind the domain of theory, and is advancing rapidly within that of the experimental method; facts are needed. Now here is a truly characteristic observation; it is that among Pasteur's adversaries there is not a single experimenter: they are all theorists and students of deceitful statistics, nothing more.

At the last Congress in Berlin, after I ended the reading of my communication upon the subject now in hand, a discussion took place, not upon the value of the preventive treatment, for its efficacy was unanimously conceded, but upon details and certain modifications connected with the method of inoculation. Professor Babes, of Bucharest, among others, reported several most interesting observations, especially this one, to which I beg to call your attention: In the environs of Bucharest a mad wolf bit thirteen people and thirty domestic animals (oxen, horses, pigs, dogs). The thirty animals died of rabies; one of the men, who had neglected to have himself inoculated, acquired hydrophobia and died also; another man died of the traumatism inflicted by the wolf, but the other eleven people who received inoculations in the Pasteur Institute of Bucharest are in excellent health now, two years after.

In Russia such observations have been repeated many times, owing to the ferocity of rabid wolves.

I may not prolong this answer, already having, I fear, trespassed upon your space, I merely affirm, with all the energy I possess, that any medical man who, in good faith, may wish to convince himself, need only look over the observations that have been published of late years and especially study the documents that are furnished every month by the *Annales de l'Institut Pasteur de Paris* (see also my article in the *North American Review*, August, 1890).

Kindly accept the assurance of my high consideration,

PAUL GIBIER, M.D.

178 WEST TENTH STREET.

A MERE DIFFERENCE OF OPINION.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: The caricaturist sometimes makes a hit at the medical profession by pretending to report the proceedings at our medical meetings, wherein Dr. A proves that such and such a course of treatment is the proper one for a certain disease; Dr. B then rises, compliments his learned brother on his admirable paper, says he agrees with him in the main, and then proceeds to show that exactly the opposite line of treatment to that advocated by Dr. A is the only proper one.

Dr. C next compliments both of the previous speakers, and then states that later investigations have proven that the plans of treatment advocated by both Dr. A and Dr. B are not only useless and old-fashioned, but are really dangerous. Then, according to the caricaturist, the discussion soon ends, leaving the hearer in doubt if anything is really known about therapeutics by any of the doctors.

Of course we doctors pronounce such articles a libel on our noble profession—that is, we tell the laity this.

Fortunately for us, the laity do not, as a rule, attend our meetings or read the medical journals.

The report in your journal of the discussion on chronic nephritis, before the Section on Internal Medicine, at the late International Congress in Berlin, might serve as a handle to our detractors were the reports printed in the secular press.

Even to the young and enthusiastic physician who had attended the meeting expecting to hear the last, final, definite word on an important subject, by these leaders of the medical profession from all parts of the world, the discussion must have been confusing if not amusing.

According to your report, Dr. Lépine, of Lyons, opened the discussion by stating that diet is of the greatest importance in this disease, and that a diet low in albuminoids is indicated. He then states that "milk is the best food for patients with chronic kidney disease." Now milk is nearly as pure an albuminoid food as we have, excepting lean beef. According to Dr. Donkin, in "Diabetes and Food," a pint of skimmed milk contains fifteen ounces of casein; and eight to twelve pints of milk (partly in curds) per day, which would be about the proper amount for a patient on a milk diet, contains a larger quantity of albuminoid food than can be taken in any other form. From all of which it would seem that there is an inconsistency between Dr. Lépine's theory and practice.

Dr. Lépine then speaks highly of the iodide of potassium in the arterio-sclerotic form of the disease; condemns strophanthus; mentions digitaline and caffeine for certain conditions; and warns against the use of the vapor-bath, for fear that it may cause uræmia.

Dr. Grainger Stewart followed Dr. Lépine. He favors hot-air and vapor-baths in cases of uræmia; knows of no medicines for the disease under consideration; favors Dr. Lépine's ideas as to diet, and uses the milk diet.

Dr. Rosenstein, of Leyden, then maintained that "no medicines are of benefit except in the treatment of complications;" diuretics in dropsy not so good as simple rest in bed; condemns calomel; and is not partial to the use of milk, which is too strong a diuretic and causes a slight gastritis.

Dr. Senator, of Berlin, agreed with all the previous speakers as to "the inefficacy of drugs in the treatment of chronic nephritis." "In certain varieties of nephritis, dependent on arterio-sclerosis, however, iodide of potassium is of real service." In these patients "this drug should be given as soon as the albumin appears."

This was something definite and would be very clear and comforting to the listener had not the next speaker, Dr. Aufrecht, of Magdeburg, stated that he had "repeatedly tried the use of iodide of potassium in these cases and had never seen the slightest benefit result from its employment."

Thus ended the discussion. In summing up we find

that Dr. Lépine favors the non-albuminous diet and keeps his patients on milk; uses iodide of potash; condemns strophanthus and the vapor-bath. Dr. Grainger Stewart favors the hot-air and vapor-bath, and the milk diet; knows no remedy for the disease. Dr. Rosenstein, is against all medicines and not partial to the milk diet. Dr. Senator agrees as to the inefficacy of drugs, with the sole exception of iodide. This is of great value. Dr. Aufrecht is certain that iodide is not of the slightest use.

In consulting the above list and eliminating those remedies that are rejected by at least one of the authorities quoted, we find we have absolutely nothing left, not even an accepted dietary.

Surely the recording angel, your reporter, if there were a spark of humor in his nature, must have smiled as he made up his report; while the young and earnest seeker after scientific certainties must have reached the conclusion that the only certainty in the therapeutics of chronic nephritis is that nothing is certain.

W. E. Forest, M.D.

THE AMERICAN DELEGATES TO THE BRITISH MEDICAL ASSOCIATION.

To the Editor of the Medical Record.

Sir: On my return from my holiday I have read with much regret the paragraph in the Medical Record for August 30th, in which complaint is made that some American delegates were treated with discourtesy at the Birmingham meeting. I issued on behalf of the Local Executive Committee a number of invitations to universities and corporations in America, requesting them to send delegates to the meeting, and asking that in each case the gentlemen appointed should forward their credentials to me. In every instance where this was complied with the delegate was invited to stay during the meeting at the house of some Birmingham citizen of good social position, was given tickets admitting him to everything open to members of the Association, and an invitation to the dinner. I also made it my business to entertain some of these gentlemen at my own house and to procure for others private invitations from the President and other local officials.

With respect to certain garden parties, it was not possible for them to be open to all members, on account of the limited space, and unless it were to be understood that nobody should give a garden party unless he could entertain fifteen hundred persons, I imagine the same difficulty will recur.

I can only express regret if any delegates from America came to Birmingham without furnishing me beforehand with proper credentials. If any dissatisfacton arose it was not the fault of the local executive, who had taken special measures to provide for the proper reception of foreign visitors, many of whom I am sure would testify to the hospitable entertainment they received here. I beg to enclose you a list of the American delegates who presented credentials to me.

I am, dear sir, yours faithfully,

Robert Saundby, M.D.,
Hon. Local Secretary.

Birmingham, September 18, 1890.

FOOT-AND-MOUTH DISEASE AND SCARLATINA: A CORRECTION.

To the Editor of the Medical Record.

Sir: In Dr. Stickler's paper on the above subject, in your issue of September 13th, he attributes to me a statement which is so entirely at variance with truth that I must crave the privilege of correcting it. To say that "foot-and-mouth disease had at times attacked nearly all the people of Great Britain," is a statement so preposterous that no one at all conversant with the facts could possibly have made it, and most certainly I never did.

To repeat what I did say, when discussing Dr. Stickler's paper before the Academy of Medicine in 1887, it becomes necessary to premise that in that paper Dr. Stickler strove to *identify* the foot-and-mouth disease with scarlatina. It was in view of this claim that I criticised his paper, and among other things I said that throughout Great Britain farmers were in the habit of purchasing their stock for winter feeding at large fairs or markets, and that as foot-and-mouth disease was perhaps the most contagious of all diseases of ruminants, the droves brought from such markets in certain years had, as a rule, brought the disease with them and contaminated the home stock. In such cases all who took the milk of the infected cows on such farms were exposed to the infection. Similarly at that date in Great Britain the city dairies were replenished at frequent intervals with cows drawn from the public markets, and already in fine condition, and these were turned over to the butcher in from two to six weeks if they contracted *lung-plague*, or in six to nine months, when the yield of the milk began to shrink, if they escaped that disease. Thus the city dairies, being all the time restocked from the public market were all the time exposed to contract foot-and-mouth disease, and as a matter of fact those cows that had passed through the limited period of acquired immunity did really contract the affection. By this means the city population were very frequently exposed to the infection, and if the diseases were identical, all persons who had not already suffered from scarlatina should have contracted the malady.

This you will perceive is a widely different claim from that so erroneously attributed to me by Dr. Stickler. He makes me say that nearly the whole British nation had suffered from foot-and-mouth disease. What I did say was that they had been exposed to the infection, and would have suffered, if the claim of the identity of the two diseases set up by Dr. Stickler had had a basis of truth. That the nation had *not* suffered proved that Dr. Stickler's claim was ill-founded.

The quotations from Sir James Paget and Professors Walley and Klein do not in the least invalidate my position; they merely meet the baseless charge made by Dr. Stickler. Not one of them denies the great prevalence of foot-and-mouth disease among farm animals in past years.

But lest any one should suppose that their denial may have a bearing on the brute as well as the human population, allow me to quote from the official records of Great Britain the number of cases of foot-and-mouth disease reported in certain recent years. The reported cases may be safely assumed to come far short of the actual ones. The report of the Veterinary Department of the Board of Agriculture claims for 1870, 457,584 cases; 1871, 691,580 cases; 1881, 183,046 cases; 1883, 461,145 cases.

As Dr. Stickler has apparently abandoned his former theory of the identity of the two diseases, it is perhaps needless to add that any such identity must have long ago told most disastrously on the flocks and herds of America. Scarlatina prevails constantly in some parts of the United States, whereas foot-and-mouth disease has been seen only at long intervals, and has always been easily traceable to the importation of diseased stock from abroad. In no case has it been impossible to trace the actual steps by which the infection advanced, and in no case was it traced to contamination from cases of scarlatina in man. In view of such facts the occasional coexistence of foot-and-mouth disease and scarlatina in England must go for naught so far as the question of identity is concerned. Either the concurrence of the two diseases was a mere coincidence, or the disease was, in man and beast alike, a simple scarlatina or a simple foot-and-mouth disease, and not the protean malady claimed by Dr. Stickler.

That the two diseases should have been confounded is

not at all surprising considering the confessed ignorance of foot-and-mouth disease on the part of physicians. Of this ignorance we have a striking example in the claim of Mr. Ceely, of Aylesbury, that a herd of cows had contracted cow-pox from infection through the bed of a deceased small-pox patient. The occurrence took place in 1840, when the foot-and mouth disease was most unusually prevalent, and the symptoms described are unquestionably those of foot-and-mouth disease, and not of cow-pox. Yet this occurrence has been quoted far and wide as a proof of the identity of the virus of variola and vaccinia.

I have not entered on the alleged prophylactic value of foot-and-mouth disease against scarlatina, but I may suggest in conclusion that, irrespective of the actual occurrence of the disease in man, the consumption of the ptomaines in meat and milk, in those European countries where this disease prevails, should render the systems of the persons who consume such food comparatively insusceptible, and should greatly diminish the susceptibility to scarlatina if the one disease is in any degree vicarious of the other. To confine our attention to Great Britain alone, the statistics of scarlatina from 1800 to 1839, a period during which there was no foot-and-mouth disease in England, should be compared with the period 1839 to 1886, during which the disease prevailed uninterruptedly. Since 1886 the disease has disappeared from the official government records of Great Britain. Children born since that date should therefore compare closely with persons living prior to 1839. If it can be shown that there is a marked difference as regards the prevalence of scarlatina in these respective periods, there will be some ground for the conclusion that that disease is affected by foot-and-mouth disease. If no such marked difference can be shown the presumption must be visionary. A demonstration on such a large scale is not likely to mislead. Respectfully,

JAMES LAW.

CORNELL UNIVERSITY, ITHACA, N. Y.,

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 21 to September 27, 1890.

KIMBALL, J. P., Major and Surgeon. In view of the early abandonment of Fort Elliott, Tex., to which post he is at present assigned for station, is relieved from duty at that post, and will, upon the expiration of his present sick leave of absence, proceed to Fort Supply, I. T., and report to the commanding officer for duty. S. O. 132, par. 2, Department of the Missouri, September 24, 1890.

Under the provisions of General Orders No. 43, c. s., Headquarters of the Army, Adjutant General's Office, the post of Little Rock Barracks, Ark., will be abandoned, to take effect not later than October 1, 1890. G. O. 15, Headquarters Department of the Missouri, St. Louis, Mo., August 11, 1890.

BROWN, PAUL R., Captain and Assistant Surgeon. To accompany Company E from Little Rock Barracks, Ark., to Fort Supply, I. T., and there take station until further orders. G. O. 15, Headquarters Department of the Missouri, St. Louis, Mo., August 11, 1890.

EWING, C. B., Captain and Assistant Surgeon. Granted leave of absence for one month, to take effect the 1st proximo. S. O. 131, par. 5, Department of the Missouri, St. Louis, Mo., September 22, 1890.

APPEL, AARON H., Captain and Assistant Surgeon. The leave of absence granted for seven days, by the commanding officer at Fort D. A. Russell, Wyo., is extended twenty-three days. S. O. 70, par. 3, Department of the Platte, September 17, 1890.

MIDDLETON, JOHNSON V. D., Major and Surgeon. Relieved from duty at David's Island, N. Y., and will report in person to the commanding officer at Fort Columbus, New York City, for duty at that station, relieving Major Joseph R. Gibson, Surgeon, and reporting by letter to the commanding general, Division of the Atlantic. S. O. 219, par. 1, A. G. O., Washington, D. C., September 18, 1890.

GIBSON, JOSEPH R., Major and Surgeon. On being relieved by Major Middleton, will report in person to the commanding officer at David's Island, N. Y., for duty at that station, and by letter to the Superintendent of the Recruiting Service. S. O. 219, par. 1, A. G. O., Washington, D. C., September 18, 1890.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending September 27, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	47	16
Scarlet fever	21	3

Pertussis	0	0

Is Hypnotism Humbug?—"I find it difficult to discuss the matter with patience. That the phenomena of hypnotism exist and that they command the earnest investigation of scientific men there is no doubt. But I do not believe the time has come to use the method as a remedial agent. We don't know enough about it. I am sorry to say I cannot draw a sharp line between some of the phenomena of hypnotism and the ideas of the spiritualists and old-fashioned mesmerists. The charlatans who use the system to humbug the public are frauds who should be suppressed. Did you ever see a collection of photographs of those people? The rogues' gallery would be a collection of gentlemen compared with them. And yet they undoubtedly have a mysterious power over certain persons. Animal magnetism won't account for it. I saw the other day the daughter of a New York physician, a delicate, beautiful young girl, completely hypnotized by one of the ugliest, most repulsive-looking Russians you ever saw."—E. C. SPITZKA.

"The first thing that strikes me in connection with hypnotism is the confidence with which it is asserted that it has been proved beyond dispute to be so successful that it cannot drop. But I am old enough to remember that this was said in the time of mesmerism. Practically, mesmerism fell into desuetude fifteen years ago. Except in distant corners such a thing is scarcely heard of. Now, from some researches which have been conducted at Nancy, and stimulated by the opposition of the Salpêtrière school, we have the subject once more brought before us, and we are told of the advent of a great and important practical truth. Therefore we are told that hypnotism has established itself for all good. I have no hesitation in prophesying that before twenty-five years have passed it will be in the same position that it was twenty-five years ago."—SIR ANDREW CLARK.

It Wasn't His Tooth.—Countryman to Dentist: "I wouldn't pay nothing extra for gas. Just lug her out. Never mind if it does hurt." Dentist: "Well, you are plucky, sir. Let me see the tooth." Countryman: "Oh. 'tain't me that's got the toothache: it's my wife. She will be here in a minute."

A Model Polyclinic.—A Western physician, desirous of supplying a long-felt want in the shape of a new medical school for his native city (population 2,400), travelled in search of information. The following bit of experience is given by him in the Cincinnati *Lancet Clinic*: "For a year past. I have noticed in the *Journal of the American Medical Association* the advertisement of a polyclinic, a clinical school for post-graduates. Being a new enterprise. I felt, of course, a great desire to see its workings, and from its name and object of teaching post-graduates I supposed that the faculty, with the exception of five or six members, whom I knew by reputation, had been specially imported, as the names of the rest were unknown to me. When I arrived at the place, I found a two-story house with a sign reaching across the whole front. Entering the front room on the first floor, I found a number of women sitting, each having a baby on her lap. On inquiring for the professor. I was requested to sit down, as he was in the next room and would be in presently. I did not have long to wait, for in a few minutes a young man came in, apparently about twenty-seven years of age, who told me, on introducing myself, that he was Professor Blank. I informed him of the object of my visit, namely, to go through the institution. I was told that he had nothing else to show me but these rooms. I asked where the lecture-rooms were. and he said they had no occasion for one, as students had not yet materialized, and the clinics were only for the benefit of the poor. On inquiring how the institution was kept up. I was told that each professor was assessed monthly for an equal share of the expenses. This is certainly the most self-sacrificing institution I have ever met. The doctors spending their time to treat people gratis, and paying monthly from $15 to $20 for the privilege of doing so."

Impurities under Finger-Nails.—The progress of bacteriology has shown that aseptic surgery means scientific cleanliness; the same lines of investigation show how very dirty people can be. Seventy-eight examinations of the impurities under finger-nails were recently made in the bacteriological laboratories of Vienna, and the cultivations thus produced showed thirty-six kinds of micrococci, eighteen bacilli, three sarcinæ, and various varieties; the spores of common mould were very frequently present. The removal of all such impurities is an absolute duty in all who come near a parturient woman or a surgical wound. It is not enough to apply some antiseptic material to the surface of dirt; the impurity must be removed first, the hand antisepticised after. Some physicians, when intending to drain dropsical legs by acupuncture or other methods, are very careful to use antiseptic dressings, and in such cases have the feet and toe-nails purified and rendered aseptic as far as possible. It is sometimes said that the scratch of a nail is poisonous. There is no reason to suspect the nail-tissue; it is more likely the germs laid in a wound from a bacterial nest under the nail. Children are very apt to neglect to purify their nails when washing hands; and this matter is not always sufficiently attended to among surgical patients. Personal cleanliness is a part of civic duty, and, as Dr. Abbott well expressed the matter in his address to teachers, should be taught to school-children and insisted on in practice. The facts we have recorded might well form the text for a school homily, especially when any epidemic was in the neighborhood.—*The British Medical Journal.*

Some Milk Statistics.—The *American Analyst* says that there are $2,000,500,000 invested in the dairy business in this country. That amount is almost double the money invested in banking and commercial industries. It is estimated that it requires 15,000,000 cows to supply the demand for milk and its products in the United States. To feed these cows 60.000.000 acres of land are under cultivation. The agricultural and dairy machinery and implements are worth $200,000,000. The men employed in the business number 750,000, and the horses over 1,000,000. There are over 12,000,000 of horses, all told. The cows and horses consume annually 30,000,000 tons of hay and nearly 90.000,000 bushels of corn meal, about the same amount of oatmeal, 275,000 000 bushels of oats, 2,000,000 bushels of bran, and 30.000,000 bushels of corn, to say nothing of the brewery grains, sprouts, and other questionable feed of various kinds that are used to a great extent. It costs $450,000,000 to feed these cows and horses. The average price paid to the laborer necessary in the dairy business is probably $20 per month, amounting to $180,000,000 a year. The average cow yields about 450 gallons of milk a year, which gives a total product of 6,750,000,000. Twelve cents a gallon is a fair price to estimate the value of the milk, at a total return to the dairy farmers of $810,000,000, if they sold all their milk as milk. But fifty per cent. of the milk is made into cheese and butter. It takes 27 pounds of milk to make 1 pound of butter, and about 10 pounds to make 1 pound of cheese. There is the same amount of nutrition albuminoids in 8½ pounds of milk that there is in 1 pound of beef. A fat steer furnishes fifty per cent. of boneless beef, but it would require 24,000,000 steers, weighing 1.500 pounds each, to produce the same amount of nutrition as the annual milk product does.

The Dangers of Exalgine.—It does not look as if exalgine, the proposed substitute for antipyrine as an analgesic, is likely to beat the latter out of the field all at once. Almost weekly we hear of a case of untoward symptoms following its administration, and nothing renders the practitioner more diffident than the knowledge of such occasional results. It must, however, in justice be borne in mind that both antipyrine and cocaine, to say nothing of the numerous other drugs of the aromatic series of recent introduction, have a good deal of this sort of thing to answer for, and they are even credited with having determined a fatal issue in quite a number of instances, a delinquency that cannot so far be laid at the door of exalgine. By and by, when we understand a little better the *modus operandi* of antipyretic and analgesic remedies, we may be enabled to eliminate some of the risks that at present seem inseparable from their use. It is not improbable that samples of exalgine of uncertain composition are in the market, the use of which may account for the disasters which have been recorded.—*Hospital Gazette.*

The Proper Place for Foreign Study.—The *Medical News* of August 30, 1890, says that human beings are so much like sheep in their habit of following where their predecessors have led that it seems almost useless to attempt to divert their course from the clinics of Vienna or Berlin to those of London, Liverpool, or Edinburgh. Yet anyone who has studied both on the continent of Europe and in England must have been impressed with a number of advantages possessed by English study over those offered in still more foreign lands. The advantage of the mother-tongue is inestimable. Very few Americans who do not possess German blood know enough of the German language to understand the terms used by a rapid lecturer in the Fatherland, and, if they do not, they lose that which they chiefly desire, namely, the minute points of the subject before them. The average American going to one of the continental clinics receives most of his instruction from docents, or other instructors of a comparatively low grade, simply because he is one of hundreds who throng, not only around the chief, but overflow to the subordinates; while in England, notably in London, the number of eminent men is so great, and the percentage of foreign students so small, that each and everyone can sit at the feet of the teacher whose writings are known everywhere in the civilized world. While the student in Berlin or Vienna becomes imbued with the views of the single individual governing a given course, in London he may go from hospital to hospital and obtain different views, and in consequence become a man of broader ideas and greater resource.

REMOVAL OF A LARGE EXOSTOSIS OF THE ORBIT, WITH PRESERVATION OF THE EYE.[1]

BY THOMAS R. POOLEY, M.D.,

SURGEON-IN-CHIEF OF THE NEW AMSTERDAM EYE AND EAR HOSPITAL, PROFESSOR OF OPHTHALMOLOGY IN THE NEW YORK POLYCLINIC.

IN offering to the Society a history of the following case of exostosis of the orbit, with an account of the operation for its removal, I desire to do so without entering into detail of the literature of the subject, which has quite recently been fully done by Dr. Joseph A. Andrews, of New York, in an admirable paper in the MEDICAL RECORD, September 3, 1887. Very few such cases are on record, and those in which successful operations have been made still fewer.

The patient, a healthy young Irish girl, twenty three years of age, first consulted me on August 21, 1888, on account of the condition of her right eye. Two years ago she first began to notice protrusion of the eyeball, and to be troubled with lachrymation. There was, however, no pain nor other annoying symptom, and she was led to seek advice mainly on account of the increasing deformity. The inner part of the upper lid was slightly prominent and pushed downward, conjunctiva and eyeball normal. There was a moderate degree of exophthalmos forward, outward, and slightly upward, with impairment of the movement of the eye inward.

Upon palpation a tumor could be felt in the upper and inner angle of the orbit, which was of bony hardness and painful upon pressure; the growth also could be felt beyond the inner wall, extending to the floor of the orbit. There was no abnormal appearance of the fundus, and with — 1 D. c. axis 180° vision was normal. There was no diplopia. The diagnosis of orbital exostosis was made. The nature of the growth and the danger attendant upon its removal was explained to her relatives. They consented that an exploratory incision should be made to determine the exact size, seat, and nature of the tumor, and the consequent dangers of its removal. This was accordingly done, but upon fully explaining the state of affairs the friends declined further operation. The incision confirmed the previous diagnosis and revealed a large ivory-hard exostosis attached to the upper, inner, and lower walls of the orbit by a broad base, firm and immovable. The patient was not seen again until Thursday, February 6, 1890, when she came to the clinic of the New Amsterdam Eye and Ear Hospital. Her symptoms were now very alarming, and she was desirous of having something done for her relief, but again deferred operation until she could consult someone else. There was now intense swelling, redness, and tenderness of the lids, with great chemosis of the ocular conjunctiva, especially below, where the swollen conjunctiva protruded beyond the palpebral fissure. The exophthalmos, too, had greatly increased and the eyeball was pushed forward, outward, and somewhat upward, and the movements of the eye greatly restricted in every direction, especially inward and downward. There was well-pronounced optic neuritis V. = $\frac{xx}{200}$.

On the night of the day following I was called to see her at her house, on account of the appearance of urgent symptoms, and now found her suffering from great pain in and around the orbit, with increased pulse, rise of temperature, nausea, and when she fell asleep, mild delirium. The exophthalmos and swelling of the lids had greatly increased, even since I last saw her, and I urged immediate operation, being under the impression that suppuration of the orbital tissue, or some acute inflammatory complication, had set in. The next morning she was admitted to the New Amsterdam Eye and Ear Hospital, and at 3 P.M. the same day I began the operation for the removal of the tumor, with the assistance of Drs. Ward, Roberts, and E. A. Kirkpatrick, the house-surgeon. An incision was begun along the upper margin of the orbit, near the middle of the superciliary ridge, and carried to the inner margin, care being taken to keep on the bone. It was found necessary to extend the incision downward to the floor of the orbit, beyond the margin of that part of the tumor which could be felt in this location. When completed, the incision was curvilinear, 75 mm. in length, and embraced about two thirds of the orbital circumference. Upon cutting through the tense periosteum the dense, yellowish-white bone characteristic of ivory exostosis was seen. There was no escape of pus or serum. The place of attachment of the tumor was now clearly exposed, and I began by the use of chisels to attempt its detachment from the upper and inner wall. To my great delight I found that a groove could readily be made in the bone with a chisel, without even using the mallet, but by merely using the ball of my hand as such, and it was not necessary throughout the entire operation to use it. I kept the chisel close to the walls of the orbit, cutting toward the bone, and, after a somewhat tedious endeavor, found that the broad base of attachment was nearly severed, and that the tumor, when seized by bone-forceps, was freely movable in the orbit. I now with the chisel cut the only remaining fragments which held it, but found it a very difficult matter to dislodge the now dissevered tumor from the orbit. This was, however, at last accomplished by turning the tumor so that its long axis, which corresponded with the vertical meridian, was horizontal; and now, by putting an elevator under it, it could be pried out. Care was taken throughout the operation not to divide any of the ocular muscles, nor to injure the eye, which during the operation was kept drawn out of the way by a spatula. The orbital walls from which the tumor had been removed were rendered smooth by the use of the chisel and the periosteum-knife. No attempt, however, was made to draw the periosteum over it. The wound was now united by six catgut sutures, except in the most dependent part, where an antiseptic rubber drainage-tube was inserted into the orbit. The usual antiseptic precautions were adhered to throughout the operation. The operation, which was made under ether, lasted about one hour and a quarter, was attended by considerable hemorrhage, and was well borne by the patient, who, upon coming from under the influence of the ether, saw well. There was no diplopia, and only some bloody discharge through the nose and mouth. One-tenth grain of morphine was given hypodermically. Antiseptic iodoform gauze, perforated by a number of holes, smeared with carbolized vaseline, a layer of borated cotton, and firm compressive bandage applied, and patient put to bed. At 11 P.M. the patient had not slept, and complained of slight pain in the orbit, radiating superiorly from it; pulse, 100. Gave ten minims of Majendie by the mouth.

Sunday, 9 A.M. — Pulse, 90; temperature, 98⅘° F. Wound dressed and found healed by primary adhesion

[1] Read before the American Ophthalmological Society, July 16, 1890.

throughout its entirety, except at the drainage-tube, lids swollen, cornea clear, chemosis somewhat lessened, vision good, some nausea, otherwise comfortable. Slept a few hours during the day. Pulse, at evening, 90; temperature, $100\frac{1}{5}^{\circ}$ F.

Monday, 10th.—Did not sleep well; wound about the same. Pulse, 84; temperature, $98\frac{4}{5}^{\circ}$ F. The patient cheerful and free from pain. Discharge takes place freely through the nose and mouth, but little through the tube.

Wednesday, 12th.—No. 3 stitch removed, as suppurative appearances were making themselves apparent in its track.

Thursday, 13th.—Had a restless night; pulse, 100, temperature $100\frac{2}{5}^{\circ}$ F.; tenderness and swelling below the right ear due to enlarged chain of lymphatics; stitch No. 2 and the drainage-tube removed, which was not replaced, as all drainage seemed to take place through the nose and mouth. Considerable thin discharge oozed through the wound at the site of No. 2 stitch, especially on pressure. In the evening pulse had fallen to 84, and temperature to 99° F.

Friday, 14th.—Patient slept well, pulse and temperature good, considerable discharge, but swelling going down and chemosis disappearing.

Saturday, 15th. — Pulse, 72; temperature normal, exophthalmos decreasing.

Sunday, 16th.—Stitches Nos. 1 and 3 removed, or at least what remained of them, as they had been partially absorbed and suppuration was appearing in stitch-canals, a natural wrinkle beginning to appear in the upper lid.

Monday, 17th.—Remaining stitches removed, considerable headache of the nature of migraine, which disappeared by evening after a dose of antipyrine.

Tuesday, 18th, Wednesday, 19th, and Thursday, 20th.—A gradual improvement without any untoward symptoms. Little ulcers have formed at the site of the stitches, and there is considerable thin, pus-like discharge through the opening at stitch No. 1. Chemosis still present, but in less degree. Red precipitate ointment spread on iodoform gauze, to be renewed three times a day, was applied to heal the little ulcers.

Saturday, 22d.—Headache again, otherwise doing well; sleeps well and has a good appetite.

Sunday, 23d.—Five grains of quinine were given to ward off the headache, which usually comes on at the same time in the afternoon, and had the effect of greatly relieving this symptom.

Monday, 24th.—Sixteenth day after the operation. Exophthalmos nearly, and chemosis entirely, gone; ulcers healed; no discharge from the wound, which is now entirely healed; eyelids beginning to assume a natural appearance; still some slight discharge through the nose; temperature normal and pulse 86; bandage left off for the first time; vision equals $\frac{20}{200}$, with $-\frac{1}{30}$ c. axis, 180°, $\frac{20}{100}$, optic neuritis almost disappeared.

On 26th.—Still improving, homonymous diplopia, which has existed in the lower part of the field of fixation since the 18th, is daily decreasing. This appears to be due to a mechanical displacement of the eyeball, since the double images do not correspond to any of the known forms of paresis of the ocular muscles, and is daily improving.

The following diagrams, kindly made for me by Dr. E. A. Kirkpatrick (Figs. 1 to 3), show the situation of the double images and a gradual diminution in the double-vision area, while Fig. 4 shows the situation of the double images in the diplopia, caused by paresis of the superior oblique, the only muscle which would have been likely to be injured during the operation.

On 28th.—Three weeks after admission, patient was discharged from the hospital. There was some conjunctival injection and swelling of lower lid, slight discharge through the nose, incision firmly healed, scar not very conspicuous, diplopia as shown in the diagrams.

March 3d.—The patient came to my office; vision $\frac{20}{40}$ without any glass, which no longer improved the sight; diplopia still exists, but does not annoy her; no longer any discharge through the nose or mouth, nor any appearance of neuritis, except that the disk is still somewhat red; no exophthalmos; free movements of the eyeballs in every direction; some lachrymation.

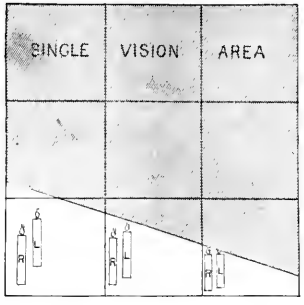

Fig. 3.

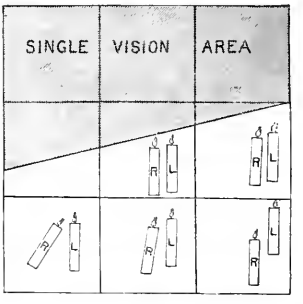

Fig. 4.

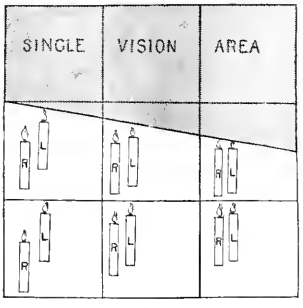

Fig. 1.

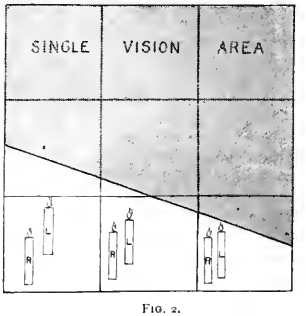

Fig. 2.

The last examination, made in my office April 29th, one day before the patient sailed for Europe, showed the following: V. $= \frac{20}{40}$ without any glasses; diplopia still exists, but the area of double images less and inconstant. (See Fig. 3.) Complains of rather frequent headaches, all evidences of neuritis gone, disk normal in appearance, but little deformity, except slight puckering of the scar where the stitches were; still some slight œdema of the lower lids and lachrymation. Since then I have had a letter from the patient, who says: "The scar is scarcely perceptible, the double images have almost worn away, and the only annoying symptom remaining is slight watering of the eye."

The tumor removed is covered with periosteum, except where it was attached, and apparently consists of compact bone throughout, except at its point of attachment, which is soft and cancellated. It is of an irregular oval, with a projecting portion which extended into the orbit, about the size of a horse-chestnut, covered with irregular nodules and traversed by numerous sulci. It weighs twenty-six grammes. (See Figs. 1 to 6.)

Its longest antero-posterior diameter (obliquely forward and a little downward) measures 39 mm. Its greatest

lateral diameter, 28 mm., and its vertical diameter, 30 mm. The base of attachment of the tumor, which resembles an irregular oval, was to the orbital walls, and the points of the attachment were, respectively, the os planum of the ethmoid, the frontal and lachrymal bones, and probably a part of the superior maxillary. Its base of attachment measures antero-posteriorly (slightly obliquely upward and outward), 27 mm. Anteriorly (obliquely downward), 24 mm. In its longest diameter, which is nearly vertical (slightly inclining backward), 30 mm. The shortest diameter of the attachment, in what may be said to constitute an irregular circle, measures 20 mm.

Figs. 1 to 6.—Surfaces of the Tumor. (Natural size.)

Whether the tumor originated in the ethmoidal cells, or was of purely orbital origin, it is difficult to say. The whole of the tumor lay in the orbit. The patient had never complained of obstruction of the nose, and no portion of the growth was extra-orbital; hence, while the point of origin of the tumor may have been in the ethmoidal cells, the entire development and extension was into the orbit. The rough surface of attachment as shown in the specimen would seem, too, to indicate its orbital origin, and does not show any extension into the adjacent pneumatic cavities. In regard to the operative procedure, I may briefly mention what seems to me to be the more important features, and first of all is the comparative ease with which the operation may be accomplished when the exostosis projects into the orbit only, and does not invade other adjacent cavities. Although, as shown by Knapp's[1] and Andrews's[2] successful cases, even here the obstacles to a successful operation are not insurmountable; but the method suggested by Knapp, of the enucleation of these tumors from their periosteal capsule, does not seem to me to have been indicated in this case. The feature in my case which seems to be of the greatest interest, and which no doubt added to the comparative ease of the operation, was the occurrence of the acute symptoms, which were no doubt due to an acute ostitis in the site of the attachment of the tumor, thus causing this part of the growth to become comparatively soft, and so to readily yield to the attacks of the chisel, and thus to do away with any necessity for the use of the mallet. To this rather than to any cerebral pressure caused by the impact of the tumor on the orbital roof, and thence on the brain, may be attributed the constitutional symptoms. In regard to the technique of the operation: The instruments used were small hand-chisels of different construction, some grooved, others straight. Spatulas and elevators. The latter were especially useful in prying the impacted tumor from the orbit when its basis had been severed; in doing which it became necessary to turn the tumor, so that its long axis corresponded with the palpebral fissure, and then to pry it out of the orbit; which proved the most difficult part of the operation. I was at times greatly aided during the operation by a small portable electric light, devised by Dr. Milton Josiah Roberts, which was so arranged as to throw a bright light into the depths of the orbit. The recovery from the operation was as favorable as under the circumstances could be expected. There was the reaction, both constitutional and local, which might naturally be expected after such a protracted operation, and although the wound had first united by primary adhesion, some little suppuration, most marked in the course of the catgut sutures, which certainly in this case seemed to be less innocuous than I have seen in the use of fine silk, occurred. The drainage-tubes seemed to have been of little if any use, for the natural drainage which took place through the nose and throat did away with any necessity for it, nor do I think that in undertaking another operation of this kind I would use one at all. The rapid disappearance of the optic neuritis, the improvement of vision, and the return of the refraction to an emmetropic condition, are all of great interest. While it is easy to account for the occurrence of neuritis, and consequent diminution of vision, I am at a loss to account for the occurrence of the astigmatism and its subsequent complete disappearance.

[2] MEDICAL RECORD, September 3, 1887.

ON THE NON-EXISTENCE OF RACHITIS IN JAPAN.

BY ALBERT S. ASHMEAD, M.D.,

NEW YORK.

ALL foreign observers agree in stating that the disease rachitis is exceedingly rare, if not wholly unknown, in the Japanese islands. A majority of them claim that it is absent. During a nineteen months' children's clinical service in Tokio, I was not privileged to meet with a single case of the disease, none presenting itself for treatment. Through my intercourse with native colleagues I found out that no such disease had ever been brought to their notice.

If rachitis, as the disease is called with us, is but comparatively rare in Japan, the reason for it is extremely interesting, in connection with the fact of the syphilitic and tuberculous infection of its people.

I shall quote from eminent foreign authorities respecting the childhood of the Japanese in some of its bearings upon, and relations to, my subject. With Dr. Simmons, I shall first unite in saying that "Japan is the paradise of children." I do not think there can be found in the world a happier babyland than this. Everything seems to have been planned especially for their welfare, and what is more, that Japanese childhood is unbounded—never ends. Old age flies kites, plays with tops and marbles, and the laws make merry playmates out of men. There is nothing in the material world which surrounds Japanese childhood to which anything like what we might call *moral* rachitis could ever be traced back in this land.

Remy, in his "Notes Médicales sur le Japan,"[1] in

[1] Archives générales de Médecine, vols. i. and ii. Paris, 1883.

speaking of this relation says as follows: "Among the details of Japanese hygiene I have been especially struck by the manner in which children are fed and brought up. They are suckled by the mother until the age of five and six years. They run after their mothers asking for the teat in a correct language. The manner in which the age of the children is reckoned may occasion an error of more than a year. However, during a long period the child depends entirely on its mother. Artificial lactation is unknown. The mother considers it a strict duty to suckle her babies." "It is with difficulty that they can be prevented when they are sick."[1] The mother's milk, however, is not the only food of the child till the age of five or six years. In the second year special aliments are added—boiled rice, river fish, sweet potatoes, cakes, boiled eggs, with the national sauce the "shoyu." But the child invariably begins by being fed, for a more or less protracted period, with the mother's milk.

The Japanese women are equal to this prolonged lactation, thanks to a very remarkable exuberance of lacteous production. The Japanese women are small; their breasts before pregnancy are not particularly developed, but after that period they are capable of producing incredible quantities of milk. The secretion is so active that the milk spurts from the teats, and pathologic galactorrhœæ are not rarely observed. There seem to have existed specialists for this affection. I saw at the clinic of the hospital of Kaga Yashiki a young woman whose breast gave six litres of milk per day. Dr. Baelz had that same milk analyzed. It was found to contain a quantity of milk-sugar and of albumin superior to the average, and its abundance had produced a state of exhaustion for which the patient had to be treated. The Japanese mothers take no other food than the national dishes. Much rice, herbaceous and farinaceous vegetables, fish, a great deal of tea, and sundry popular stuffs. In Japanese houses they make tea forty or fifty times in a day. This prolonged lactation weakens the mother, who looses early the freshness of youth. Perhaps it may account also for the small average of fecundity given by the statistics, the women remaining fifteen and seventeen months without menstruation. According to Dr. Baelz's statements large families are scarce, they do not go beyond three or four children. I am speaking of the children of only one woman, for as custom allows the husband to add concubines to his household, the number of scions may thus increase proportionally. Besides the prolonged lactation, let us note, as a cause of the weakness of average fecundity, abortion.

In spite of the strain on them the mothers submit to prolonged lactation with laudable maternal devotion. As to the children, such a diet is productive, as a rule, of a flourishing state of health. They are stout and plump. However, it would not be advisable to found one's judgment solely on the countenance of the Japanese child. That is always rounder than shown by the European type, and preserves a puffed appearance of health even when the rest of the body has become emaciated. The influence of such an alimentation, however, does not preserve the child from all diseases. Yet it is easy to understand that with such a diet it need not fear that gradual dwindling away through insufficiency or bad quality of the aliments which is called athrepsy. It escapes the gastro-intestinal affections which make so many victims in our country. Nevertheless there is a great mortality. I was not able to obtain exact statistics, to compare with our own figures of mortality, but I believe the Japanese proportion to be smaller, because it is not easy to find for a wet-nurse a woman who has lost her child. When children die it is generally from pulmonary and cephalic affections. Hydrocephaly[2] in all it forms is very frequent; some children are born with sutures already separated and with a conformation of the head indicating internal exudations. With most of them the affection takes place only after birth. As autopsies are seldom practised in Japan, it is difficult to find the real cause of the affection. Is it the manifestation of an hereditary tuberculosis? Is it the result of imprudent practices, of the absence of all protection to the head of the new-born against a burning sun? I shall have to return to this subject by and by. It seems to me that if the custom of lactation saves a number of children, on the other hand, there are other habits which expose them to other dangers. Every nation has its faults as well as its good points.

"There is, however, a result of the lactation which I would above all clearly represent. *The rachitic does not exist in Japan I never met him, neither among the children nor among the adults; neither in city nor in country, nor in hospitals. The physicians, native, and foreign, whom I consulted, are aware of no single instance.*[1] It is, so to speak, an experiment made on a whole nation, and the conclusion from it is this: Rachitism may be avoided by feeding the child with the maternal milk. It might be objected that this absence of rachitism is due to the law of natural selection; that all weak children died at a tender age. But if this were true in Japan, why should it not be equally so in Europe, and why should not our rachitics disappear also? It may be said that hereditary syphilis is the cause of rachitism. But this disease exists in Japan as well as elsewhere, and yet it does not make rachitics. The difference of alimentation, the exclusive lactation of the young Japanese is, in my opinion, the cause of this difference between the infantile pathology of this country and all other countries, the bad hygienic conditions are merely accessories."

Dr. Wernich,[2] in his chapter on Pregnancy, Childbirth, and Confinement of the Japanese,[3] states as follows: "The Japanese girls and women conceive uncommonly easily, as experience shows. Besides, they are capacitated for an especially fertile work of propagation by their vivacious, though moderated sensuality—which does not, as a rule, spend itself in a short time, as it does in men—the favorable build of their bodies, and the long duration of the child bearing period. It is assumed that the power of conception and propagation stops only toward the fiftieth year, which may be a little exaggerated but is certainly not very far from the truth. We shall treat of the diminution of the power of conception by the long suckling when we speak of the latter in the next chapter. Those cautious attentions by which the Japanese women are guarded in every form of life, and have come to be regarded as duties, are increased twofold during pregnancy. A multitude of ceremonies and rules of conduct, which at the first glance seem to be sheer superstition, take, when more closely considered, the shape of dictates of a quite reasonable puerperal dietetic. The woman is forbidden to eat certain dishes difficult of digestion—mustard, salad, salad-seed, ground fresh turnips with vinegar, salmon, whale, and some crustaceæ. Excessive sexual intercourse during pregnancy is also warned against, 'because it may result in phthisis during confinement.' Some of these prescriptions, it is true, border on the burlesque, and bear a grossly unphysiological stamp. Thus, the pregnant woman ought always to lie with bent legs, even during sleep; lest the fœtus put his legs into those of the mother, as in a pair of breeches, the legs of the sleeping woman were tied together with bands, in order to keep them in that bent position. For the ascertainment of the pregnancy the cessation of the menstruation was considered the surest symptom, and

[3] Geographische Medical Studien. Reise um die Erde. Berlin, 1878. (Journey Around the World.)

this event was made the starting point for the chronology of the pregnant state. With the official division of the year into lunar months the calculation was simple, in so far as from the first absence of the menstruation ten lunar months were counted as required by the whole course. Strange to say, the women were puzzled when the last menstruation reached from the closing days of one (calendar) month into the first of the next Zekimatangi, a technical expression especially invented for that case. The calculation was then incorrect, as they counted the commenced month as a full one. Now the women count by days—two hundred and eighty days—but they admit that they blunder a great deal."

A pregnant person is considered everywhere as an object of delicate regard, a being worthy, that is, in need of every assistance. It was this feeling which made the building of a new lying-in asylum a useless expense, while otherwise it was proper to be quite enthusiastic about founding hospitals on the European plan, and to spend much money for that purpose. The higher magistrates, with whom this point was discussed, said: "The building for the lying-in asylum would be easily enough obtained, but they were at a loss to see who was to enter it." No class, no condition, no combination could be imagined in which a Japanese woman approaching childbirth would not find the most tender nursing either in her own family or in that of the father of her child. The poorer she is, the easier her modest claims to a quiet little place for her heavy hour can be satisfied. The smallest hut and the janitor's house of every palace would receive at once any woman suddenly seized with labor, even if she was a total stranger. To these arguments could only be opposed what is to be said in favor of our own lying-in asylum. I insisted, in these negotiations, on the fact that confinements always carry off a smaller percentage of victims in places where competent professional aid was ready at hand. I tried to show that this professional skill could only be taught and learned on the cases themselves; that, finally, in order to be able to communicate these traditions to pupils well and thoroughly, such an institution was the proper place. The Japanese protected themselves with half-true arguments and many specious ones. Those pathological conditions, they said, occurred seldom in Japan; *there was no osteomalacie in the country, very rachitic persons got no husbands, the children were generally small and found their way easily into the world.*[1]

In the higher classes they admitted there occurred very frequently difficult confinements, but the difficulties were then of so peculiar a nature that the European physicians themselves would have been puzzled by them (this observation referred evidently to the difficulties in the shape of the pelvis). As to the instruction, they said the bulk of the pupils might receive the necessary demonstration on the model. Only a few of them would become good obstetricians anyhow, and these would easily find opportunities for further improvement in their private practice. After some battling I gave up the hope to see a lying-in asylum of higher degree added to the other hospitals approaching completion. I should not have thrown up the sponge so easily if some secret considerations had not stopped it, and they regarded puerperal fever. The more I investigated the more I found that puerperal fever, in the sense of the English, French, and German literature of the first sixty years of this century, *has never existed* in Japan. I may now add, in agreement with most impartial obstetricians, *because there never was a lying-in asylum in the country*, and even the want of such an institution or of a surrogate, according to the popular views just mentioned, was never felt. Every woman, even the poorest, is delivered in solitude, in the smallest, perhaps unhealthiest room, but nursed by a *nurse who cares only for her*, not threatened by the frightful poison which unclean utensils, unclean instruments might communicate to her; still less by that which, after a slow accumulation in a room which has been saturated for months by secretions suspended in it in the shape of dust, suddenly displays its deleterious effect. Nor is she exposed to the most disgusting, the most murderous of all, the cadaveric poison which sticks to the unclean fingers and clothes of the clinical and medical students, running from the operating table and the microscope to the childbed, and transplanting the infectious matter with cruel certainty on the swollen, half-wounded, mucous membranes of the vagina and womb. *I consider the fact that no endemic or infectious puerperal fever has appeared in Japan up to this day as irrefragably proved.*[1]

In the first place there exists, in no writing, no tradition, the slightest allusion to any knowledge of such disease. Taking into account the care with which the Japanese writers have treated every circumstance relating to the birth of children, it would be strange that a murderous disease, arising during confinement and spreading over a ward or over a whole city, should have escaped them. As already stated in the note, they know pretty much all confinement diseases which interest us, besides the puerperal fever, but the latter is unknown to them. It is not a fallacy if I add further, to establish the fact of the non-existence of puerperal fever in Japan, the certain absence of those factors which more and more are recognized as active in its production. There are no autopsies, or they occur seldom, and there are no lying-in asylums. From a medical fact so surely established cruel arguments against the lying in asylum and against the method of our medical teaching might be deduced. However, the condemnatory sentence against the frivolous promiscousness of pathological obstetrics has already been pronounced under the leading of the immortal Semmelweiss, and the voices which, on account of the sad experiences made every day in the palaces of confinement, clamor more and more for a change in this branch of study.

What has been pointed out formerly by Stolz, and of late by v. Grünwald, in regard to the favorable experiences made in the *small* Petersburg asylum, I hope to confirm strongly by the facts mentioned above. If the *solitary* puerperal woman cannot be made use of more extensively for the instruction of students than is done now; if we are sure to limit the natural mortality by timely and manually excellent operations in the lying-in asylums, let these houses be established at least on as small a scale as possible, and banish the medical student occupied with anatomical researches of any kind in the most peremptory way from the rooms of these small asylums.

The Japanese female pelvis is broad and very spacious, hence labor is naturally easy. Wernich found in his gynecological studies,[2] that in the eleven obstetrical cases which he observed from beginning to end, the cause of a difference in the course was *never* pathological deformation of the pelvis.

The oscillations in the relation of the conjugata to the approximately equal values of the circumference (the latter *always* inferior to the European standard, owing to the Javanese-Malay difference in stature) related to the general build and size of the individuals. Dr. Dowitz put before the East Asiatic Society tables and cuts of pelvis orifices in which crista deviations of 28.1, 26.9, 26.6, with conjugata values (conjugata vera) of 10.1, 9.4, and 9.3 are opposed to other pelves with 25.8, 23.7, and 24.0. Distantia crist. oss. il. and respective conjugata of 10.4, 10.8, and 10.9. The broad pelvis he compared with the European, the deeper one with that of the Malay.

Deformations of the female pelvis in Japan are exceedingly rare; pelvic deviations are usually natural and racial, *the rachitic pelvis is unknown*. Remy, in a paper entitled "Des Japonnais," in speaking of the modifications of the body due to special habit says, "The way of sitting down is quite peculiar; the Japanese kneels down, turns the tips of the feet inside, and rests the seat on the heels. The inferior extremity of the tibia, the articulation

[1] The italics are mine.—A. S. A.]

[2] Medico-Surgical Academy, Tokio, 1874.

of the tarsus, the external border of the foot support directly the weight of the body, the knees participate indirectly in it. The ligaments of the knee, and especially those of the tarsus, are stretched, the head of the astragalus is prominent.

The habit of carrying the foot tip in the adduction in order to sit down, continues even in walking, especially with women, but fashion has something to do with it also; it is the *ne plus ultra* of good form. Some deformations observable in a small number of Japanese, and which consist in an excessive divergence of the knees and a kind of stunted development of the arms, have been explained by this manner of sitting. The small length of the arm of the Japanese, compared with the rest of the body, has been pointed out by Mme. Chaplin-Ayrton[1] and she explains it by the habit to take the shoulder for a point of support to lift burdens and by the habit of crouching.

The pillow is a block of wood 10 ctm. high, 5 ctm. broad, covered with a cushion. It was necessitated by the hair-dressing, which was only renewed every three days, and was put on the neck. It causes a very uncomfortable distention of the neck. Some artists, seeing that the neck of the Japanese, especially the women, is always very slender and graceful, have ventured to seek the cause of it in the use of that instrument."

These deformations are national, and are due to habits alone. I think that those observers who claim to have seen cases of rachitis in Japan have confounded some of these deviations. Many of them, like the bow leg or "sabre-leg" of the Japanese, come from their manner of sitting on the floor. In childhood the soft bones readily yield and observe new directions. Or like the pressed ribs and prominent sternum of the babies, are induced by their mode of carriage on the backs of older children, the retaining band which holds the child on—a figure-of-eight bandage about the ribs—compresses them. None of these national deformities are allied *in any manner* with rachitism.

"According to twenty-six observations made by Dr. Scheube and by M. Tagachi, a Japanese anatomist,[2] the length of the intestine is greater in Japanese than in Europeans. If we compare the length of the body with that of the intestine we come to astonishing results: To 100 ctm. of stature in the European correspond 506 ctm. of intestine; to 100 ctm. of stature in the Japanese correspond 607 ctm. of intestine. It is an augmentation of a fifth."

From time immemorial the Japanese have been fishers, and hunters, and tillers of the soil. Their diet has consisted largely of fish and other products of the sea, the crustaceæ, and iodized seaweed, of which they have always eaten abundantly. As a people they have most beautiful and well-formed teeth. It is the exception in Japan to find youth associated with decay of teeth. Surely the Japanese alimentation has operated to secure to the race sound teeth and bone, at least. Fish is supposed to be rich in phosphorus or its surrogates, and is recommended to us as a brain-food; but never, that I know of, has it been suggested as a remedy—a bone-food—in osteomalacia.

The Japanese have always eaten plentifully of fats and oils of fishes, the blubber of the whale, the eel, and loach especially; and these have contributed their measure in procuring for the nation such an immunity, and endowing it with a greater degree of sound bone formation. The universal use of the food under notice, from the time of ancient Buddhist flesh prohibition, but especially the consumption of fish by the lactating women, together with the fish given to the children after their first year, as supplement, which at that time is allowed them by Japanese tradition, are, in my opinion, main causes of the non-existence of rachitis in Japan.

[1] Thesis of Paris, 1878.

In the order of their sequence may be cited some additional factors.

1. Absence of deformed pelves in the women of Japan, and heredity thereof, hence easier gestation and labor.

2. Exceedingly gentle care and nursing of the pregnant and parturient women.

3. National possession of finer teeth, consequently more perfect mastication and emulsion of aliment.

4. Increased length of intestinal absorption-surface, hence freer chylification.

Various writers strongly advocate the use of phosphorus, with cod-liver oil, to eradicate rachitic tendencies.

Professor Jacobi, in a note addressed to me, advises the oleum phosphoratum of the United States Pharmacopœia to be given in the oil. May I suggest it behooves us to learn the lesson which Japan thus teaches us, adding to this sound treatment by the phosphorized cod-liver oil a general and more constant lactation, checking that prevailing tendency to wean prematurely, and adopting a fish diet for both mother and child.

SOME NOTES BEARING ON THE ADMINISTRATION OF IRON.

By JOHN AULDE, M.D.,

PHILADELPHIA, PA.

Although iron is highly esteemed as a medicament, and is largely used for its tonic effect upon the system, so frequently does it occur that the patient objects, owing to some idiosyncrasy or fancy, that we cannot regard it wholly as an ideal hæmatinic. No apology, therefore, is required in offering to the profession a comparatively recent preparation, which is free from some of the objections that have been urged against many of the iron preparations now in use. In order to make the reasons which I have to offer clear and distinct to the casual reader, I have deemed it wise to consider briefly some points intimately connected with the pharmacology of the drug. From this preliminary study we shall be in a measure prepared to estimate how nearly the new product comes to meeting the defects with which we have had to contend so long, and at the same time it may possibly lead to a more intelligent use of this well-known remedy.

Besides the reduced iron, we have in general use the ferric and ferrous preparations, the latter being more mild, less astringent, and free from the objections to the ferric salts—that of coagulating albumin. Lethal doses of the ferric salts used intravenously, in experimental investigations, cause almost immediate paralysis of the central nervous system, fall of blood-pressure, and death. Although the perchloride, when thus used, causes instant death by coagulation of the blood, it does not act in this direct manner when introduced subcutaneously; the nerves are unaffected, but at the points of elimination inflammatory action is set up, *e.g.*, the kidneys, liver, and intestinal mucous membrane show more or less effect.

Absorption takes place as a peptonate or albuminate, but it is taken up so slowly that no appreciable result follows, unless, as just stated, it may be used intravenously or subcutaneously. Absorption takes place more rapidly in catarrhal conditions of the intestinal tract—a fact to be borne in mind when exhibiting large doses, which cause gastro-intestinal catarrh. Small doses do not have this effect, nor does the metal appear in the urine from their administration, such as may be observed after the ingestion of large doses. It will be inferred from the foregoing that by the exhibition of small doses of a soluble preparation of iron it will be assimilated without causing derangement of the alimentary tract, and in this way the secondary effects, *i.e.*, the deposit of the metal in the system, may be avoided.

The fact should be kept constantly in view, that metals have a poisonous action upon nerves, nerve-centres, mus-

cles, and upon all glandular structures; and as iron is a reputed hæmatinic, much harm may result from its injudicious employment, as there are evidently certain toxic effects following the long-continued use of insoluble preparations. This is a rule which applies especially to all insoluble iron preparations, and it is but reasonable to assume that, whatever harm has been done through this means, may have escaped attention, because few physicians are likely to investigate the presence of factitious diseases. Another factor which has contributed to lessen these evils, is the slow process of absorption.

The foregoing observations apply with equal force to the effects of the drug upon the circulatory apparatus. While copper is an active agent in causing contraction of the blood-vessels, iron produces slow contractions, showing that it is less irritant (stimulant) to the nervous system. This may possibly be accounted for on the hypothesis that iron is a normal constituent of the blood. Whether this effect is due to irritation (stimulation) of the vaso-motor nerves, central or peripheral, or to a direct action upon the muscular walls of the blood-vessels, is a question still in doubt. My own impression is, that through the influence of the medicament upon the nerve-cells the large doses, comparatively, arrest their function, when contraction of the muscular structures in the vessels takes place. The ferric salts, owing to their property of coagulating albumin and blood, of course produce more marked effects than the ferrous salts. Digitalis and ergot among the organic, and barium chloride among the inorganic, remedies, well-known as vascular tonics, furnish apt illustrations of this important principle.

Iron has a tendency to accumulate in the liver; small doses do not show this tendency, but they may serve to increase the functional activity of this organ, when given in a soluble, non-astringent form, by restoring cell-nutrition to the normal.

The effect of iron upon muscular structure has long been known to experimental physiologists, but I doubt if this knowledge is appreciated by many practitioners, who regard the possible benefits to be derived from the exhibition of iron preparations in proportion to the amount tolerated by the patient. Now, large doses, while they do not affect the irritability of muscular structure, lessen materially the amount of work it is capable of performing, while small doses increase the capacity of muscle for work. What is most to be desired, therefore, is a preparation not open to the objections inferred from these investigations; but owing to the necessity for consulting the palate of our patients, it is also desirable that the substance should be free from the nauseating effects which are so common to all preparations of iron. The combination I believe is to be found in that form known as levulose ferride, which was highly recommended to me several years ago by my friend, Dr. James Collins, of this city.

The preparation known as levulose ferride is one which takes the place of a well-known and popular German product, called *Eisenzucker* (iron-sugar), very extensively used in domestic practice. I was led to the employment of iron-sugar on account of its palatability, fastidious patients and children making no objections to it; but this has been supplanted by levulose ferride, which in the form of tablet triturates will be taken as readily as chocolate bon-bons. It is readily soluble in an excess of water, and practically free from any ferruginous taste or styptic effect when dissolved in the mouth, and is substantially a peptonate. The method of preparing it is briefly as follows: To a certain amount of iron a measured quantity of malt-sugar (maltose) is added, and the mixture constantly stirred while exposed on a water-bath. While it possesses all the desirable qualities mentioned, the presence of metallic iron may be determined by chemical analysis, the strength of the product being about three per cent.

This preparation, it will be apparent, will act much less actively as an astringent than even the ferrous preparations; but, of course, it cannot be expected to take the place of the ferric products, which are sometimes demanded, as in the case of intestinal parasites (sarcina ventriculi and lumbricoides). On the other hand, it will be especially indicated for the relief of anæmia and chlorosis, owing to its ready absorption, lack of astringency, and its palatability. In all cases of defective nutrition, from any cause, where the ingestion of any form of medicament is a trial to the patient, this product will be kindly received. A synopsis of some of the cases in which it is indicated, together with a summary of the effects following its employment, may prove interesting to the physician.

During the early summer months, I had under observation a young mother with a six-months old child, who presented a very anæmic condition. I had seen her but once since the delivery of her child, and anticipating that she would not be able to nourish it sufficiently and maintain her health, I had cautioned her in regard to the most appropriate diet. Notwithstanding every care had been used, she was finally compelled to seek medical aid, or go to bed. All that this patient required was something for the purpose of increasing the amount of hæmoglobin, which would restore the integrity of the red corpuscles and improve the oxygen-carrying capacity of the blood. This being most readily accomplished by levulose ferride, she was ordered to take tablets of this preparation, each containing three grains, after meals. To meet the emergency, and increase the patient's strength until such time as the advantages of the iron would be apparent, small doses of strychnine (one-sixtieth grain) were administered along with the iron. Ordinarily, this class of patients, when they begin in the early summer, suffer more or less from the effects of the heat, and become regular patrons of the doctor; but this patient did not make her appearance again for about two months, when she said she thought it was about time to have a little more of the same medicine. I may mention in passing that the first medicine was sufficient only to cover the first ten days, and the patient seemed greatly disappointed that she was compelled to return.

So many children are so promptly benefited by the use of a small quantity of iron, that it is a great drawback to us that no palatable preparation has been discovered and put on the market. I have in mind a little fellow who has long been very much averse to eating meat, due, I presume, to defective digestion; but for the past few weeks, since he has been taking the levulose ferride, he seems quite content to eat meat alone, and is becoming strong and robust. Not long ago I had a visit from a lady, who brought with her a young lad, aged fourteen, who had a most forbidding cadaveric expression, and he could eat no meat. His brother, I was told, had died at about this age from Bright's disease, and this one presented all the symptoms peculiar to the brother who died. Still, with attention to diet, out-door exercise in the country, and a tablet triturate containing three grains of levulose ferride after meals, he made a prompt recovery. Although I was unable to discover any symptoms of Bright's in this instance, I was impressed with the depression due to the anæmic condition; and yet, without some readily assimilable iron preparation it would have been a tedious process to start him on the way toward recovery.

Late in the spring of the year, a gentleman aged about thirty-five called on me, complaining of dyspepsia, although he had been under the treatment of another physician for overwork for the preceding four years. After regulating his diet, and adopting treatment calculated to restore the activity of the digestive apparatus, he was placed upon levulose ferride along with strychnine sulphate—three grains of the former in tablet form, and one-sixtieth grain of the latter, and did remarkably well on this combination. This product, like all other mild preparations of iron, is mostly indicated in cases of this class, and along with these may be mentioned chorea, convalescence from lingering diseases, like typhoid fever; and in all such instances, I venture to anticipate that the

results will be especially favorable where proper attention is given to dietetic measures.

The administration of the remedy may be confined to the use of the powder, which is taken dry on the tongue, dissolved in water or coffee; or it will be found more convenient in the form of tablets, each containing three or five grains. The dose for children ranges from three to ten grains, and for adults from five to thirty grains.

1010 ARCH STREET.

REPORT ON ARISTOL.[1]

BY CHARLES W. ALLEN, M.D.,

SURGEON TO CHARITY HOSPITAL, NEW YORK CITY.

ARISTOL is described as a thymol iodide and is a discovery of Drs. Messinger and Vortman of Aachen. It is a brownish amorphous powder, produced by the addition of a solution of iodine in iodide of potassium to an alkaline solution of thymol. From a knowledge of its composition we are at once led to hope that aristol would present the necessary qualities of an antiseptic nature to bring it into general use as a rival of, if not a substitute for, iodoform and iodol. Iodoform has such disagreeable qualities that, in genito-urinary cases especially, it has become difficult of employment in private practice. We are therefore inclined to hail with welcome almost enthusiastic any substitute which promises to act with equal efficacy and, while devoid of its disagreeable odor, possesses the good qualities of iodoform.

Aristol has been highly extolled on the other side of the Atlantic in various quarters, but till now I have seen no report of its employment here. I have therefore jotted down my impressions of the new preparation in the cases in which I have given it a trial. When I announced a paper on the subject I had expected to remain at work in the city during the summer and continue my observations. As it is, I have been absent the entire time and hence my report is necessarily incomplete.

For some time prior to using it in any strictly dermatological case I had been applying it as a dressing to such surgical wounds as would ordinarily be treated with iodoform, and had been pleased with its action, although at times it proved too stimulating. In a case of injury to the index finger with considerable loss of tissue, more than half the thickness of the finger having been cut away, I succeeded by the use of aristol in producing sufficient granulation tissue almost to fill up the gap. At one time the granulations became so exuberant that I was forced to cease its use and apply the silver stick lightly to the surface.

In a number of cases of wounds requiring sutures, and in others drawn together by adhesive strips, I have sprinkled on aristol freely, and always with good results.

For some months I have had on my office-table a ten per cent. solution in collodion and have applied it as a protective antiseptic dressing to that class of cases in which I usually apply benzoated collodion or iodoform—excoriations, lupus after burning or scraping. (After scarification I always apply mercurial plaster.)

I have dusted the pure powder upon large flat condylomata and then painted over a coating of the drug in collodion with the best results.

Iodine possessing such curative virtues in certain lesions of syphilis, I made a trial of aristol in one case of gummous ulceration of the nasal mucous membrane with perforation of the septum, blowing in the powder with an insufflator. This the patient learned to do very well for herself and the healing process seemed to be hastened more than would be accounted for by the internal medication alone. It is in this way capable of being applied in a very thin even layer and is non-irritating Dobell's solution was used to remove crusts and secretions as occasion required. Schuster, of Aachen, describes this same use of the powder in the May number of the *Therapeutische Monatshefte* The experience of others has, I think, shown that what theoretically one would be led to expect of aristol in open suppurating or moist lesions of syphilis, has been in a great measure realized in a practical way.

In the out-door department of Bellevue Hospital I treated thirteen cases of chancroid with aristol alone. Seven of them are marked on the book as either "cured" or "improved." A careful history of the cases was not kept and I do not know the subsequent history of the other six. My own impression, however, as well as that of my assistant, Dr. Crowley, was that the new remedy acted in a beneficial way and that the sores were healing as rapidly as were those subjected to the usual forms of treatment. A chancroid of the abdominal wall—the size of a half dollar, treated in my Charity Hospital service by aristol alone, healed in a most satisfactory manner after thirteen days.

Neisser, on the contrary, has found aristol to have no action in chancroids, and Brocq says its employment does not seem to exert a favorable modification of the virulence of the disease. The experience of Meyer of Berlin, however, corresponds more closely with my own, which further observation will confirm or not.

An extensive ulceration of the buttock, resulting from burning with nitric acid in which the patient had accidentally sat down, healed under applications of powder and ointment, but only after forty-eight days' stay in hospital. The result here was not as flattering as it had promised to be at the outset, the more superficial parts of the burn having cicatrized with great rapidity. In the central portion, where there had been deep sloughing, the granulations became too exuberant and flabby, and strapping after light application of silver, was resorted to for a time to flatten the surface. Several cases of psoriasis, one of eczema, one of seborrhœal eczema, and one of eczema barbæ were improved under the ointment or paint, but no especial advantage was noted over other forms of treatment. Psoriasis was not so much nor so rapidly improved as other similar cases under chrysarobin or as the parts treated by chrysarobin for comparison upon the same individual.

In a case of persistent bromide ulceration in an epileptic girl, healing was quite rapid under aristol when under permanganate, ointments, and other applications it had shown little or no improvement.

In a case of persistent chancre-like ulcer following vaccination (probably from some form of mixed infection), granulation and cicatrization were quickly established. In one case of vulvitis in a little girl the application of the powder after thorough cleansing acted well.

In syphilitic ulceration of the scalp the results were apparently very good. A deep ulcer of the dorsum pedis, resulting from a burn, healed under the use of aristol powder in a prompt and satisfactory manner.

I prescribed a fifteen grain to the ounce ointment in an extensive case of chromophytosis occupying the whole abdomen and chest. I did not see the patient again, but he was reported to me as having been cured.

In an ulcer of the leg, three-quarters of an inch in diameter, healing took place under the powder in three or four days, but another ulcer on the under surface of the great toe in the same individual was but little benefited. In one case of acne, after incising the papulo-pustules and pressing out the comedones, I used a five-per cent. ointment in vaseline with what seemed to be beneficial effect.

There were three cases of erysipelas treated by aristol (reported in my paper on erisipelas read at the same meeting). One, in an infant of three weeks, proved fatal on the third day, a result to be anticipated from any method of treatment. The other two cases, one of facial erysipelas and one of erysipelas of the extremities and trunk in a child nineteen months of age, recovered after one week's treatment respectively. In several other cases

[1] Read at the meeting of the American Dermatological Association, September 4, 1890.

aristol was applied as a powder to the wounds from which an erysipelas had originated, and with good results.

In one case of eczema rubrum and ulcer of the leg a ten per cent. and subsequently a twelve per cent. ointment acted well and the case rapidly recovered. In another case of ulcer of the foot, there was little if any improvement after treatment had been continued for some time. While the powder was being applied scarification was practised upon the calloused margins of the ulcer by the house surgeon, and was followed by an attack of erysipelas of the leg. This was regarded by the operator, Dr. Andrews, to whom I am indebted for notes of cases, as an evidence of the non-antiseptic properties of aristol. The scarification had been done, however, without the usual preliminary washing with a bichloride solution to remove all impurities. In this connection it is interesting to note that Neisser has found experimentally that aristol powder and salve possess no antibacterial qualities. Several other ulcers of the leg were treated at the hospital with indifferent results. Applications of the powder followed by a ten per cent. ointment produced in some chronic indolent ulcerations more tendency to granulation than had been noted in some time.

As to the mode of employment of aristol, being insoluble in water, and but slightly soluble in alcohol, its use in solution is restricted to preparations made with the various oils, ether, chloroform, collodion, etc., in which it dissolves readily. Being freely soluble in oils and fats, it can be made into ointments and salves with lard, lanoline, vaseline, etc., and can even be used as a paste made with starch. If free iodine were present, a reaction would take place, which I have not found to be the case either when aristol is mixed with powdered starch or made into a paste. I have, however, not made trial of such combination therapeutically. Langgaard makes the rule that aristol should never be combined with substances for which it has a chemical affinity. Among the latter are enumerated caustic alkalies and alkaline carbonates, ammonia, metallic oxides, and corrosive sublimate. In ulcers, excoriations, and open wounds I have used it mostly in the powder form, often applying a thin coating, and over this simply vaseline or a two to five per cent. aristol ointment. In some cases, however, it appears more desirable to apply the dry powder and allow a crust to form. In conclusion, I may say, as the result of my observations up to the present time, that in aristol we have an excellent application for the various ulcerations of the skin; that it possesses valuable cicatrizing and granulation-stimulating qualities, and being devoid of irritant properties, and free from disagreeable odor, can be used with advantage in that class of cases formerly treated with iodoform. It is of decided benefit, also, in a certain, though somewhat limited, number of strictly dermatological affections, which future experience may extend.

606 Madison Avenue, New York.

The Deadly Cold Bed.—If trustworthy statistics could be had of the number of persons who die every year, or become permanently diseased from sleeping in damp or cold beds, they would probably be astonishing and appalling. It is a peril that constantly besets travelling men, and if they are wise, they will invariably insist on having their beds aired and dried, even at the risk of causing much trouble to their landlords. But the peril resides in the home, and the cold spare room has slain its thousands of hapless guests, and will go on with its slaughter till people learn wisdom. Not only the guest, but the family often suffer the penalty of sleeping in cold rooms, and chilling their bodies, at a time when they need all their bodily heat, by getting between cold sheets. Even in warm, summer weather a cold, damp bed will get in its deadly work. It is a needless peril, and the neglect to provide dry rooms and beds has in it the elements of murder and suicide.—*Druggists' Circular.*

Progress of Medical Science.

Malarious Africa.—Malarial fever is the one sad certainty which every African traveller must face. For months he may escape, but its finger is upon him, and well for him if he has a friend near when it finally overtakes him. It is preceded for weeks, or even for a month or two, by unaccountable irritability, depression, and weariness. This goes on day after day till the crash comes—first cold and pain, then heat and pain, then every kind of pain, and every degree of heat, then delirium, then the life-and-death struggle. He rises, if he does rise, a shadow, and slowly accumulates strength for the next attack, which he knows too well will not disappoint him. No one has ever yet got to the bottom of African fever. Its geographical distribution is still unmapped, but generally it prevails over the whole east and west coasts within the tropical limit, along all the river courses, on the shores of the inland lakes, and in all low-lying and marshy districts. The higher plateaus, presumably, are comparatively free from it, but, in order to reach these, malarious districts of greater or smaller area have to be traversed. There the system becomes saturated with fever, which often develops long after the infected region is left behind. The really appalling mortality of Europeans is a fact with which all who have any idea of casting in their lot with Africa should seriously reckon. None but those who have been on the spot, or have followed closely the inner history of African exploration and missionary work, can appreciate the gravity of the situation. The malaria spares no man; the strong fall as the weak; no number of precautions can provide against it; no kind of care can do more than make the attacks less frequent; no prediction can be made beforehand as to which regions are haunted by it and which are safe. It is not the least ghastly feature of this invisible plague that the only known scientific test for it at present is a human life. That test has been applied in the Congo region already with a recklessness which the sober judgment can only characterize as criminal. It is a small matter that men should throw away their lives, in hundreds if need be, for a holy cause; but it is not a small matter that man after man, in long and in fatal succession, should seek to overleap what is plainly a barrier of Nature. And science has a duty in pointing out that no devotion or enthusiasm can give any man a charmed life, and that those who work for the highest ends will best attain them in humble obedience to the common laws. Transcendentally, this may be denied; the warning finger may be despised as the hand of the coward and the profane. But the fact remains—the fact of an awful chain of English graves stretching across Africa.—*Drummond.*

Treatment of Rupture of the Uterus.—In an article by Dr. Berry Hart, on this subject, we are told that, in cases of rupture where the presenting part is still in the genital tract, it is evident we must deliver it in such a way as to avoid upward tension on the uterus, and therefore craniotomy or decapitation should be quickly employed. If the rent is not extensive, local irrigation with a dilute corrosive lotion, drainage, and abdominal pressure, or tamponnade of the uterus, vagina, and rent, with iodoform gauze should be performed; when the rent is more extensive, the edges should be approximated with tenacula while the tampon is being applied. With an extensive tear and escape of child and placenta, or any one of them, into the cavity, laparotomy is imperative for extraction and peritoneal toilet. Extensive tear means bleeding into the peritoneum, and great risk of ultimate septicæmia if the blood be not removed. The treatment of the extensive rent is the next question. Suturing alone is ineffective, takes long, and has not been followed by good results. It is in such that our choice lies between Prevôt's amputation or careful tamponning vaginally and peritoneally with iodoform gauze. In sixteen cases of this amputation five recovered. Leopold, however, has

recently recorded a case where the rent involved three-fourths of the lower uterine segment, and where the uterus was only attached by the left broad ligament. In this case laparotomy was performed, the pouch of Douglas plugged with a long strip of iodoform gauze, which was applied to the edges of the tear, brought round between the right side of the uterus and pelvic wall into the vesico-uterine pouch, and its end out at the abdominal wound. The uterine cavity and vagina were plugged with another strip. These were left in for fifteen days, and the patient made an uninterrupted recovery. In seven cases treated thus, Leopold saved two. Hence we should all endeavor to give such cases the chance that operative treatment holds out. Many of them are hopeless, but even the most skilled prognosis is sometimes at fault, and it is not the duty of any man in such emergencies to fold his hands and say the case is hopeless, the woman must be left to die.—*Edinburgh Medical Journal.*

Trephining for Cerebral Hemorrhage.—Dr. Championnière recently reported to the Académie de Médecine a case of trephining for cerebral hemorrhage, together with statistics of thirty such cases, all of which were non-traumatic in their origin. There had been no deaths and no untoward occurrences. The new case was that of a man, fifty-three years of age, who had had an attack of cerebral hemorrhage twenty months before. Right hemiplegia ensued, together with late contracture of the hand and epileptic seizures. The focus of disturbance in the brain was localized at the middle part of the precentral convolution. Cranio-metrical measurements were made, in accordance with the results of which trephining was performed. The remains of an old cerebral hemorrhage were found and removed. Antiseptic precautions were duly observed, and drainage was provided for. Time of operation, one hour and a quarter. The next day the contracture of the hand had ceased, and the hemiplegia showed marked improvement. Speech was more distinct, and the patient also showed greater intelligence. During four months he has had no return of the convulsions, from which, previous to the operation, he had suffered at least as often as once in two weeks. *Gaillard's Medical Journal.*

Causes of Hæmaturia.—In 100 cases the causes were as follows: Renal calculi, 30; enlarged prostate, 20; vesical calculi, 14; tumors, mostly malignant, 13; tubercle, 6; urethral stricture, 5; non-prostatic cystitis, 3; passage of calculi through ureter, 3; traumatism, 2; filaria sanguinis hominis 1; doubtful, 3.—REGINALD HARRISON in *Medical Press.*

The Action of Cod-Liver Oil.—Drs. Gautier and Mourgnes, in a recent communication to the Academy of Sciences, discuss at some length the reasons why cod-liver oil is superior to other fats as a therapeutical agent, and arrive at the following conclusions: 1. It is more easily assimilated, owing to its containing free fatty acids and some biliary matters which render its emulsion specially easy when it comes in contact with the pancreatic juice. 2. It is rich in phosphates, phosphoric acid, lecithin, and phosphorus in organic combination; the phosphorus, especially in the last-mentioned form, is very readily assimilated to form protoplasm, and thus nutrition is greatly stimulated. The small amounts of bromine and iodine being also present as organic compounds exercise a beneficial influence on the general metabolism. 3. The alkaloids present—butylamine, amylamine, morrhuine—and morrhuic acid stimulate the nervous system, increase the amount of sweat and urine, and act as nervine tonics.—*The British Medical Journal.*

Fatal Poisoning with Salol.—Dr. Hesselbach has reported the case of a young man suffering with rheumatism, who took by mistake two drachms of salol. Coma resulted, with great dryness of the tongue, anuria, and death on the second day. At the necropsy the kidneys were found to be soft, anæmic, and of a pale yellow color; microscopically, the glomeruli were full of embryonic cells and leucocytes, the convoluted tubes were tumefied, and fatty degeneration had begun. The tubuli were filled with degenerated epithelium. There were no other lesions attributable to the drug. The toxic principle was the carbolic acid that is generated from salol in the system. The author believes that salol should be prescribed with caution, and the condition of the kidneys, as indicated by the urine, watched.

Statistics of Austrian Hospitals.—According to recently published official statistics, the number of hospitals in Austria in 1887 was 568, showing an increase of 11 as compared with the preceding year. The total number of patients under treatment in these institutions was 300,422, being 6,001 in excess of the number in 1886. Of these, 67.8 per cent. were cured, 16.1 per cent. relieved, and 5.8 per cent. unrelieved, while 10.3 per cent. died. Of particular diseases, syphilis took the lead with 24,522 cases, tuberculosis coming next with 17,790; one-third of the total number of deaths in all the hospitals together is credited to tuberculosis, while syphilis was accountable for only 0.31 per cent. In the 18 lying-in institutions 16,736 mothers, and 15,086 infants were cared for, the death-rate being 0.93 per cent. among the former and 5.21 among the latter. The asylums for the blind were 10, with a population of 706, of whom 17.2 per cent. were born blind; outside these establishments there were 14,798 blind persons, of whom only 2.2 per cent. were inmates of special institutions. The total number of cretins was 14,798, most of whom, of course, belonged to the Alpine districts.—*British Medical Journal.*

A Cruel Experiment.—Count Zorouboff, a medical man of scientific aspirations, has recently been charged with the sequestration of four children of tender age, upon whom he was carrying out a series of experiments of comparatively little value. In order to test whether children brought up without hearing the human voice would speak, he placed the children in confinement under the charge of a deaf-mute, and the children were growing up as he expected. The German law fortunately came to the aid of the children, and they were rescued, though the count escaped deserved punishment, as he had otherwise treated the children with care. He has, however, to provide for the children in the future. Supposing that some experimentalist captured the count, and carried him off to some castle to carry out experiments on the count's own body—say, to test the count's power of endurance under the lash, or how little food he could exist on, we think the count would hardly appreciate the scientific value of his experiments; or if the count had children of his own, he would hardly submit them to the class of experiment he was trying on the unfortunate children he became possessed of. The moral sense must be very much perverted when such experiments can be even thought of, and we regret to say that a large number of experiments performed at the present day have even less justification than is to be found for Count Zorouboff's investigations.—*Provincial Medical Journal.*

The Influence of Female Employment Upon Marriages, Births, and Deaths.—So far as English vital statistics throw light upon this subject, they appear to show that in counties where the proportion of women engaged in industrial pursuits is large, the ratio of early marriages, as well as the actual marriage-rate, is high; and that as a natural consequence the birth-rate is also proportionally high. With regard to the death-rate, we have at present no statistics which enable us to judge of the influence of female employment upon the mortality of women, but it is an undoubted fact that the rate of infant mortality is abnormally high in most of those counties in which the ratio of women engaged in industrial occupations is much above the average. The last annual report of the Massa-

chusetts Statistical Bureau, in dealing with the subject of industrial employment among women, supplies some information relating to its influence on marriage, birth, and death-rates, which, if mainly of a negative character, cannot be said to be without interest. After careful examination of the statistics of female employment in fifty cities and towns containing more than sixty-four per cent. of the total population of the State of Massachusetts, the opinion is expressed that employment of women in industry has not decreased the number of marriages or of births, and that neither has it increased the number of deaths. With regard to the proportion of women employed in "gainful occupations," it is stated that whereas in 1875 it was 21.3 per cent. of the whole, it had increased to nearly thirty per cent. in 1885. Stated in another way while the female population had increased 17.7 per cent. in the ten years, the number of employed women had increased 64.6 per cent. English census statistics showed a considerable increase of female employment between 1871 and 1881, but it is very unlikely that the results of the census next year will show a proportional increase of employment among women approaching that shown by the Massachusetts statistics. The influence of female employment upon marriage and birth rates, and upon mortality, is one which well deserves more careful investigation than it has yet received.—*The Lancet*, September 20, 1890.

Hairs as Records of Emotional Disturbances.— Dr. Pineus, of Berlin, claims to be able, by the aid of the polariscope, to detect certain traces of past emotions in the hairs. He explains that under the influence of mental disturbances of a violent kind the hairs become decolorized at the junction of the lower two-thirds with the upper third, reckoning from the surface of the skin to the root of the hairs. The observation, if exact, is interesting, but the recollection of such emotions is generally too vivid to render any artificial aid to memory necessary. If Dr. Pineus could only devise a means of detecting emotions to come, his *procédé* would excite a vast deal more curiosity.—*Medical Press.*

Milk Secretion in the Newly-born.—According to the observation of Dr. Variot, all infants, male as well as female, secrete a certain quantity of milk soon after birth. This usually attains its maximum during the second week where the mammary glands are prominent, the skin covering them is of a pink hue, and pressure causes pain. He observes that abscess of the breast is almost as frequent in infants as with nurses, a rather startling statement which the experience of every-day practice hardly bears out. Before the eighth and after the fifteenth day the liquid is serous rather than milky, and in this form the secretion may be prolonged as late as the fourth or fifth month. This observer failed to detect an analogous condition among the young mammifera of other species.—*The Medical Press.*

Observations on Sunburn.—Sunburn on the snow has been the subject of an interesting investigation by Dr. Robert L. Bowles. Alpine climbers concede the curious fact that sun on snow burns more quickly than on rocks or in heated valleys at a low elevation, and Dr. Bowles remarks that sunlight reflected from freshly-fallen snow acts much more energetically on the skin than that reflected from older snow. Dr. Bowles one brilliant day painted his face brown, and ascended the Gorner Grat, where there was much snow. There were about eighty others making the ascent. In the evening all excepting Dr. Bowles were smarting from the effects of sunburn. He points out that in Morocco, and all along the north of Africa, the inhabitants blacken themselves round the eyes to avert ophthalmia from the glare of the hot sand. In Fiji the natives abandon their red and white stripes when they go fishing on the reef in the full glare of the sun, and blacken their faces. In the Sikkim hills, also, the natives blacken themselves round the eyes as a protection from the glare of the sun on newly-fallen snow. Dr. Bowles concludes that heat is not the direct cause of sunburn, but that it is probably caused by the violet or ultra violet rays of light which are reflected from the snow.

Alcohol and Alcoholic Solutions in the Abortive Treatment of Herpes.—In a thesis published by Dr. Dupas, of Lille, the following directions are given for the treatment of this common and often troublesome condition: Alcohol of ninety per cent. strength, or a solution of two parts of resorcin to one hundred of alcohol, can be employed as a dressing; or, one per cent. of thymol or three per cent. of menthol in ninety-five per cent. alcohol. If the solutions cause too much pain a little cocaine may be added. Compresses moistened in one of these solutions are to be applied upon the lesions, and over this spread some impermeable material, or absorbent cotton may be used. These dressings must be changed frequently during the day. The herpetic eruption aborts rapidly under this treatment. The element of pain is also subdued, and it is not rare to see rebellious neuralgias from herpes zoster give way in a few hours to this treatment.—*Journal of Cutaneous and Genito-Urinary Diseases.*

Insanity and Bright's Disease.—Dr. Alice Bennett has made a thorough study of the relations between Bright's disease and insanity, and in an exhaustive paper read before the Pennsylvania State Medical Society draws the following conclusions: 1. That, contrary to the generally received opinion, affections of the kidney are very common among the insane. 2. That "uræmic poisoning" is one of the most frequent causes of insanity. 3. That while the mental manifestations may be as varied as there are different centres subjected to irritation by these unknown poisons, the most prominent and constant symptom is some form of mental pain, which may range from simple depression, through all degrees and varieties of delusions of persecution, self-condemnation, and apprehension, with or without hallucinations, up to a condition characterized by a frenzy of fear, with extraordinary motor excitement, and rapid physical prostration—the "grave delirium" or "typho-mania" of some authors. 4. That the motor centres are specially liable to be affected, as evidenced by the restlessness and incessant activity of many cases, less frequently by convulsions and convulsive twitchings; occasionally by choreic movements; occasionally by cataleptoidal states. Dr. Bennett cites a large number of cases in support of her deductions.—*Medical News*, October 4, 1890.

Autographism.—At a recent meeting of the Académie de Médecine, M. Mesnet referred to four patients, of whom he had made special inquiries, and who presented the singular phenomenom to which the term of autographism has been given. On the slightest touch the skin is reddened, so that by passing a pencil over different parts of the body reliefs of varied forms are provoked. The cases noticed by Mesnet all came from families highly nervous and presenting persistent symptoms of deranged peripheric sensibility, analgesia, insensibility of the mucous membranes at their point of origin, and often functional disorders of the organs of sense, especially of sight and taste. All four cases showed well-marked symptoms of hysteria and were easy subjects for hypnotism. M. Mesnet considers the phenomenon is purely reflex, but not transitory, as it persists for years and is not infrequently confounded with urticaria, being indeed styled "artificial urticaria," but it differs from urticaria in being unconnected with a diathesis.—*The Medical Press.*

"**Hay Fever**," said the Moderator, at the Influenza Convention, "may be likened to a tie vote."

"Hear, hear!" cried the audience.

"The eyes and nose both appear to have it."

MEDICAL RECORD:

THE PATHOLOGY OF PHTHISIS.

THE whirligig of time has brought before us many changes in the views held as to the nature of phthisis pulmonalis. First there was the Galenical view that phthisis was an inflammatory and ulcerative disease, then came the doctrine of Laennec, Louis, and Rokitansky that phthisis was a specific tubercular disease and only incidentally and secondarily inflammatory. Then, under the influence of Reinhardt, Virchow, Niemeyer, and others, the medical world was nearly persuaded that phthisis was a caseous pneumonia, or, in other words, essentially an inflammatory process. Then came the discovery of Koch, which completely rehabilitated the old specific tubercular theory and placed it apparently upon an absolutely sound foundation. Pathologists, the world over, have without exception accepted the view of the pathogenesis of phthisis as given by Koch.

But now some doubters arise. Dr. Heneage Gibbs and Dr. E. L. Shurley have published in the *American Journal of the Medical Sciences* some papers in which they assert that phthisis and tuberculosis are absolutely distinct processes.

Phthisis, according to Dr. Gibbs, is primarily a broncho-pneumonia; tuberculosis consists primarily of giant-cells inclosed in a reticular stroma. Both the broncho-pneumonia and the tubercle may break down and form cavities; but whereas in phthisis tubercle bacilli are found uniformly from the beginning, in tuberculosis no bacilli can be found until after caseation begins. Dr. Gibbs calls in question the accuracy of Koch's experiments and denies the identity of the lesions of artificial tuberculosis with those found in the human subject.

While Dr. Gibbs asserts that phthisis is histologically distinct from tuberculosis, and that the two diseases are associated with the same bacillus, Dr. Shurley tries to establish a clinical distinction between pulmonary phthisis and pulmonary tuberculosis. The arguments presented by these gentlemen are by no means convincing, but their reputation as pathologists and clinicians entitles them to a fair hearing.

WHY NOT VACCINATE ON THE LEG?

THE following remarkable order has been issued by Health Commissioner Wickersham, of the Chicago Health Office:

"Hereafter the medical inspector of this department will vaccinate no one on the leg without special instructions from the commissioner."

In explaining this absurd order the good doctor is thus reported:

"It could not be helped. The fashion had grown beyond the bounds of reason, and this department will recognize it no longer. On Saturday afternoon six girls, two of them young women, came here to be vaccinated. They told the inspector that they wanted the operation performed on their legs. 'We don't want to disfigure our arms,' was their excuse. The girls were vaccinated as they desired. But that's the last," said the doctor, bringing his fist down on the table, "I want no more of them and won't bear them. If any girl is so fashionable that she is afraid a vaccination mark will detract from her beauty in an evening dress, she had better go to a private physician and have the operation performed in private. The old fashioned way is good enough for this office, and that's what the young women must put up with. The only exceptions in the future will be on my recommendation, and the applicant must make a personal request to me. If there is any reason why she should be vaccinated on the leg instead of the arm it will be done. You have no idea of the number of applicants there have been for this sort of thing lately. I believe it is a 'fad,' nothing more."

With all due respect for the doctor as an efficient health officer, he has evidently transcended his function in arbitrarily forcing his personal views upon the public. Even in this enlightened age vaccination is a tribute of respect by the public to the scientific demonstration of its protective power against epidemic small-pox. With a goodly number, however, it is simply a toleration of a method of practice which, from their point of view, is open to many objections. In other words, with the majority of good citizens it is just popular enough to hold its own as a health measure. Is it not safer, then, to let well enough alone rather than court unnecessary antagonism?

What right has the otherwise zealous public official to settle the question in an official way that school children shall be vaccinated on the arms only? Has the public no rights in the matter? What real objection is there against vaccinating upon the leg? Every child has a right to choose the part of the body on which to wear a life scar. Detraction from beauty is always a sufficient reason why one portion of the body should be substituted for another. If the child has the misfortune to be poor, that is no reason why her wishes should not be consulted. The arrogant repudiation of individual rights in this matter deserves a rebuke from the public. The commissioner owes it to his official position and to his profession to apologize for this unwonted assumption of power. His position is unreasonable and untenable.

SULPHATE OF CINCHONIDIA.

WHEN quinine was held at extravagant prices in this country several years ago, many attempts were made to introduce substitutes for it in the shape of its allied alkaloids. Most physicians were successful enough with these substances, but just as soon as quinine became cheap, the use of it was at once resumed. Of late years we hear

nothing of cinchonine, quinquinia, dextro-quine, and numerous others of the succedanea formerly in vogue.

A French physician, Dr. H. de Brun, of Beyroot, Syria, has, however, recently taken up the study of the sulphate of cinchonidia in a very serious and scientific spirit, and brings forward facts which will, he thinks, make a great revolution in the general prescription of the cinchona alkaloids. Dr. de Brun is Professor of Medicine in the College at Beyroot and physician to the French Hospital and general dispensary. He has had abundant opportunity of studying the comparative effects of quinia and cinchonidia, for malaria in all its forms is very prevalent.

With regard to the use of quinine, Dr. de Brun found it sufficiently efficacious, but he not very rarely met cases in which toxic symptoms were produced. He states also that there is a very great prejudice against the drug among the Syrians, on account of the tinnitus, deafness, and other unpleasant symptoms of cinchonism. Besides all this, the price of quinine was such as to prevent its general use in the dispensary and among the poorer class.

Dr. de Brun was led to select cinchonidia as a substitute for quinine not only on account of its cheapness, but because of the recommendations of previous observers, such as de Segrais, Weddell, Bourru, and Gubler, the last of whom states that a hypodermic injection of three grains of cinchonidia is equal in efficacy to one or two grammes of quinine by the stomach.

A great deal of quinine now comes from bark grown in Ceylon and Java. These barks are very rich in cinchonidia, for which there is hardly any market. Hence the price is very low. Quinine costs about fifty cents an ounce. Cinchonidia costs (in Syria) only seven or eight cents an ounce; in this country sixteen or seventeen cents.

Dr. De Brun reports in detail (in the *Revue de Médecine*, September, 1890) the histories of fifty-eight cases in which cinchonidia was used. The patients suffered from quotidian or tertian ague, with, in many cases, the classical signs of subacute or chronic malarial poisoning, also from larvated forms of ague with neuralgic attacks. Some of the patients had already been treated unsuccessfully with quinine.

The conclusions reached are that sulphate of cinchonidia, given in the same doses as quinine, combats the acute accidents of impaludism just as well as quinine. The drug is of equal value to quinine also in malarial cachexia anæmia, enlarged spleen, and visceral congestions; and in malarial neuralgias. Sulphate of cinchonidia is successful in some cases after quinine has failed. It is more soluble in water, and is less irritating to the stomach, and less easily causes ringing in the ears, deafness, and other symptoms of cinchonism.

It has usually been thought that cinchonidia was about one-third weaker than quinine. Even if it were only this, it would be a cheaper drug, as its cost is two-thirds less. Dr. de Brun, however, is convinced that the drug stands on a par therapeutically with quinine.

IS IT CHARITY?

During the year 1889 it is stated that over one hundred thousand patients were treated at the Vanderbilt Dispensary. The total number of patients treated at all the dispensaries of this city, according to the official lists, in the *Medical Register*, was, in 1889, about three hundred and fifty thousand, exclusive of those treated in the dispensary referred to. If the figures are correct, then within two years the medical paupers of the city have suddenly increased from 350,000 to nearly half a million. In other words, one out of every three or four inhabitants of the city receives medical advice gratis. Curiously enough, while the annual catalogue of the College of Physicians and Surgeons announces 102,000 patients treated in 1889 at the dispensary referred to, the *Medical Register* gives the number as 29,723. The same authority credits the Eastern Dispensary with the largest number of patients, viz., 61,228, and after this the New York Dispensary, 44,331, and Bellevue, 39,889.

Whatever be the true figures, it is evident enough that our medical charities, so called, are growing apace.

THE COLONIZATION OF EPILEPTICS.

Much attention has been and is still being paid in Europe to the care of epileptics. The physicians of Belgium seem to be especially alive to the needs of this unfortunate class. Three years ago M. Masoin made a report to the Belgium Royal Academy of Medicine upon hospitals for epileptics, and a special commission, composed of MM. Crocq, Hambursin, and Masoin have made a much more extensive report upon the hospitalization of epileptics, the extent to which it had been carried out in different countries, and the advantages of hospital or colony treatment of this class.

In Belgium there are estimated to be about four thousand five hundred epileptics among the six million inhabitants of that country. At that rate there would be between forty and fifty thousand of these unfortunates in the United States. Many of these have attacks but rarely, and are able to live with their families in comparative comfort. But the great majority become eventually enfeebled in mind, irritable, morose, and dangerous. Their seizures are a source of constant apprehension and terror. They are unable to earn a livelihood, and the lack of mental and physical occupation makes them worse. Yet they can find no hospital or special institution which will receive them, except workhouses and insane asylums.

The immense help and comfort afforded by special institutions for the care of epileptics has been amply proved by their success in Germany and France. Prussia, in particular, has done much in this direction, and has twelve epileptic institutions all erected by private initiative.

The best known of these is the colony of Bethel, founded by a clergyman, Pastor Bodelschwingh, in 1867. It has been described by Dr. Frederick Peterson, who has himself forcibly urged the need of a colonization of epileptics in this country. France has also two Bethel colonies for epileptics similar to, but smaller than, those of Germany. Beside this, she has the almost equally famous Teppe Asylum, founded by Count Larnage in the year 1857, and confided to the direction of the Sisters of St. Vincent de Paul.

Aside from Germany and France, modern nations have made but little special provision for epileptics, and we do not find our own country much behind England, Holland, Belgium, or Italy.

There are needed, however, homes for epileptics; places in which they can be comfortably taken care of, properly treated, and kept employed. Here is an opportunity for beneficent charity.

THE NARGHILÉ AND ITS SMOKERS IN THE EAST.

DR. P. EMIRZÉ, Physician to the Armenian Hospital at Smyrna, has contributed to the *Nouvelle Iconographie de la Salpêtrière* an interesting study of the effects of narghilé smoking among Eastern people. The narghilé, or water pipe, is the chief or only method by which tobacco is used in the East. Theoretically it seems as if it ought to be the safest and most harmless form of nicotine indulgence. That it is not so, Dr. Emirzé's observations seem to show.

The narghilé, as used in Smyrna, consists of a bowl for holding the tobacco, from which a tube runs down into a vessel containing about two quarts of water. To this is connected a flexible tube with mouth-piece so arranged that by suction the smoke is drawn through the water. In the water are placed a few leaves of eucalyptus or laurel. The tobacco used is specially grown and prepared. It is cut into small pieces and macerated a short time in water, then dried, when it becomes ready for smoking. The amount employed and the strength are not told us, but it seems that the smokers, if very temperate, use two or three narghilés daily, while, ordinarily, four to eight or ten pipes are smoked. Forty patients, observed by Emirzé, had smoked eight to ten pipes daily for over twenty-six years.

The effects of smoking the narghilé are similar in most respects to those resulting from using cigars and cigarettes. The nervous and local symptoms are developed somewhat more slowly, but eventually are very severe. Besides this the extra inspiratory effort required to draw the smoke through the water-pipe, produces a degree of emphysema, which may become quite marked.

The disorders of the air-passages and lungs were, according to Dr. Emirzé, numerous and severe. Among 100 subjects, aged from twenty-five to thirty-five, who had smoked four to seven narghiles daily for five to ten years, he found emphysema in 23, chronic bronchitis in 18, pharyngeal catarrh in 26. Among 100 subjects, aged thirty-six to forty, who had smoked from six to ten narghiles daily for ten to fifteen years, there was a most pronounced emphysema and chronic bronchitis in 14; 2 had tachycardia, and 1 paralysis of the trigeminal nerves. Among 60 subjects, who had smoked eight to ten narghilés for fifteen to seventeen years, there were 4 cases of bronchiectasis, with fœtid expectoration; and 5 cases of hypertrophy of the heart, with valvular lesions, were observed.

Dr. Emirzé's observations, which included 300 cases, led him to the conclusion that the narghilé smoked in great moderation, that is to say, once or twice daily, is not only not harmful, but may be beneficial as a form of respiratory gymnastics, and as an expectorant. Smoked in any excess, however, it induces chronic pharyngeal, laryngeal, and bronchial catarrhs, angina pectoris, and pulmonary emphysema.

THE DESTRUCTION OF MICROBES BY AMŒBOID CELLS—PHAGOCYTOSIS.

A YEAR or two ago Professor Wilham Osler gave an interesting address in this city upon the subject of phagocytosis and Metschnikoff's theory of the battle between the leucocytes and the pathogenic micro-organisms. At that time it seemed that this theory, while a most suggestive and original one, could hardly stand the brunt of scientific criticism. Since that time it has continued to occupy the attention of pathologists, and it still holds its place among legitimate objects of scientific inquiry. In other words, it has still neither been completely established nor demolished. In view of this fact any new contributions to the subject are important, and among those is a brief communication from Dr. M. Armand Ruffer (*British Medical Journal*, August 30, 1890), entitled "Notes on the Destruction of Micro-organisms by Amœboid Cells."

Dr. Ruffer first studied sections of the Peyer's patches of rabbits, removed with antiseptic precautions, plunged at once into absolute alcohol, and then stained with carmine and gentian violet. He often found, crowded in between the layer of epithelial cells which lines the inner surface of the mucous membrane, leucocytes holding micro-organisms in their substance. He found the same bodies in the submucous tissue. He also found there lymphoid cells in various stages of enlargement until they were finally developed into those enormous cells which have been described usually as epithelioid. These large cells are, however, what Metschnikoff calls macrophages, while the smaller are the microphages. The macrophages sometimes contain in their protoplasm the microphages and also micro-organisms in various stages of disorganization. The leucocytes (microphages), as Ruffer believes, wander out to the surface of the lumen, seize the micro-organisms, and bring them back to be destroyed by the macrophages. Even the large cells in some lymphoid structures (tonsils) may wander to the surface and absorb microbes there.

Dr. Ruffer concludes that—1. The wandering cells of the lymphoid tissues of the alimentary canal have the power of proceeding to the free surface of such tissues and of taking into their interior micro-organisms and foreign matter (charcoal, etc.). 2. There are two kinds of wandering cells in the lymphoid tissues of the alimentary canal: *a*, microphages (small mono- or multi-nucleated cells; *b*. macrophages (large mono-nucleated cells). 3. The macrophages are developed from the small mono-nucleated lymphocytes. 4. Macrophages are able to swallow microphages (leucocytes), and to destroy and digest them. 5. The micro-organisms are rapidly destroyed in the interior of the micro- and macro phages. 6. Micro-organisms are never found lying free between the cells, or in the blood-vessels and lymphatics. 7. The destruction of micro-organisms taking place in the normal lymphoid tissues of the alimentary tract resembles, in all particulars, the destructive process following on the inoculation of pathogenic organisms into resistent animals.

Dr. Ruffer asserts, from further experiments, that the large epithelioid cells of the spleen, lymphatic glands, and those of the lungs, are really macrophages developed from the lymphoid cells. The giant-cells of the infec-

tious granulomata (*e.g.*, tubercle) are also thought to be of the same origin and function, and a tubercle is only a small battle-field between microbes and phagocytes.

Dr. Ruffer is evidently somewhat of an enthusiast upon the subject of the phagocytosis theory. There is, it should be remembered, a good deal of evidence to show that many microbes are killed in the vital fluids of the body, and that the microphages and macrophages only carry off the remains.

SURGEON-GENERAL JOSEPH D. BRYANT AND THE STATE GUARD.

It will not be possible for any medical man in the State to read the report of Surgeon-General Bryant, in the "Annual Report of the Adjutant-General of the State of New York," without a feeling of personal interest and pride in the Medical Corps of the State Guard. Nowhere else, except perhaps in the State Insane Asylums, is the care for the health of so many intrusted to so few. When this is considered in connection with the well-known fact that during times of war more men die from disease than fall by the hands of the enemy, it is a matter of surprise and gratification to know that, of the six thousand *en route* to, and present at, the State Camp at Peekskill, no one has died, and no form of disease peculiar to aggregated bodies of troops has caused apprehension to the medical officers, so thorough have been the sanitary precautions.

Surgeon-General Bryant again calls the attention of the Adjutant-General to the pernicious practice of issuing to recruits uniforms soiled and out of repair, that have been worn by men previously connected with the service, who may have been dismissed for dereliction of duty; and to the advisability of requiring a physical examination to be made of all recruits to the Guard. There can be "no sadder spectacle than that often witnessed in the State Camp, of men who, by reason of permanent physical incapacities, though with transient periodical manifestations of the same, are forced to a personal exhibition of these infirmities that is distressing to themselves and their friends, and demoralizing to their associates." It is not generally known that it is possible for a man deformed with Pott's disease and still wearing a brace, to gain admission to the National Guard; such however is the lamentable fact, as we ourselves have witnessed. There can be no question in the minds of the profession, and there ought to be none in the minds of those in authority, as to the necessity of immediate and radical reforms in the directions indicated.

Quackery as a Fine Art.—A representative of *The Times and Register* has been interviewing certain much-advertised quacks, who do business in this city as well as Philadelphia. Catarrh seems to be their specialty. At least they found a bad form of it in the perfectly healthful nasal and pharyngeal mucous membrane of the reporter. They proposed to treat and cure it in eight months, charging $15 for the first month and $9 for each of the remaining months. In consideration of the offer of a photograph and testimonial of cure the price was reduced to $12 and $7.

News of the Week.

Penal Code, Section 193.—According to the rulings of the court,

"If a surgeon, for the welfare of a patient, deems it best for him or her to perform abdominal section and death ensues, malice can, under subdivision 3 of Section 193 have him indicted for manslaughter in the second degree.

"If a surgeon neglects to perform abdominal section, when in the estimation of another it should have been performed, and the patient dies in consequence of the pelvic conditions, that surgeon, under subdivision 3 of Section 193 of the Penal Code, can be found guilty of culpable neglect and indicted for manslaughter in the second degree."

This seems to place the conscientious surgeon in rather a difficult position. Dr. Vander Veer, in discussing the subject of the medico-legal aspect of abdominal section, states that in his opinion the rulings of the Court are just and necessary, and he comes to these conclusions: 1. That we should exercise the greatest care in the examination of our cases of doubtful diagnosis. 2. That when in doubt we should lay great stress upon the necessity of an exploratory incision, and make a very proper explanation of what this means to the patient and friends. 3. That in the cases thus far brought to trial we have reason to believe that the judges in their rulings have treated our profession with great fairness, the strong points being, that the public good is not subserved by undue and wilful persecution of the surgeon who has shown the proper amount of intelligence in his profession. 4. That we should seek still to have the law so made in our favor as to eliminate the cases of wilful prosecution. 5. That in the careful study of these cases we have presented the lamentable condition of expert testimony. Men absolutely ignorant upon the subject, men who have never done an operation of any merit in surgery, being allowed to come upon the witness stand and testify as experts.

Dr. Peter Hood, of London, died recently in his eighty-second year. Dr. Hood was the author of several works, notably one upon gout and rheumatism, which was republished not long ago.

The Eyes of Eye Surgeons.—At the dinner of the Ophthalmological Section of the International Medical Congress at Berlin, Professor Hermann Cohn, of Breslau, showed a collection of autographs of the oculists who had taken part in the annual meetings at Heidelberg for twenty years, which was made specially interesting by the fact that opposite each name the signatory's visual power with the right and left eye respectively was indicated. Among other celebrities who figured in this list were Arlt, Horner, the elder Critchett, Schweigger, and Knapp. Among 44 oculists tested, visual acuity was normal in 32, over the normal in 10, and under it in 2. Twenty-eight, or sixty-one per cent., were short-sighted; the concave glasses required varied between Nos. 5 and 24, the average being 20, so that the myopia of the distinguished ophthalmologists in question was, as a rule, moderated in degree.

The Medical Practice Law of Minnesota has now been in existence for seven years. The law requires examination by a State Medical Board before a license to practise can be had. The effect of the law upon the relative number of physicians in the State is interesting: In 1883 the ratio between physicians and inhabitants was 1 to 650; according to the register just published the ratio is 1 to 1,250. The ratio for the whole United States is 1 to 520, so that when compared with the rest of the country Minnesota appears to offer a favorable field for the physician seeking a place in which to settle. Those who believed, says *The Northwestern Lancet*, that the Minnesota statute was class legislation, and cried out against the passage of the law because it would allow the medical profession in the State to shut out outsiders, will no doubt seize upon the relative decrease in the number of physicians in the State as proof that the objections to the law were well founded. An examination of the records of the Board of Examiners shows that the decreased proportion of physicians has not been due to the rejection of candidates, but to the fact that the knowledge of the existence of the law has greatly decreased the number of applicants for license. The State of Minnesota is entitled to great credit for its progressive attitude toward medical education and practice. Its local schools were among the first to insist upon longer and graded courses.

Poisoning by Bromæthyl.—Three cases of poisoning by bromæthyl have lately taken place in Berlin, and Dr. Mittenzweigs, in the *Journal for Medical Officers*, warns people against the employment of this narcotic in dentistry, where it has been much used, as well as in small surgical operations, until proper experiments have been made. In the cases of poisoning above alluded to, the doses had not been more than about twenty grammes.

The Medical Profession of Louisiana has again failed with the State legislature in the matter of a law to regulate practice.

Professor Metschnikoff, of Odessa, the distinguished Russian bacteriologist, has been appointed head of the Pasteur Institute in Paris, under the general direction of M. Pasteur.

Rush Medical College.—The Chair of Medical Practice in the Rush Medical College, Chicago, made vacant by the death of Professor J. Adams Allen, is said to have been offered to Dr. Henry M. Hyman, formerly Professor of Chemistry and of Diseases of the Nervous System in the same institution. Dr. Harold N. Moyer has been elected to the professorship of physiology.

The Missouri Medical College celebrated its semi-annual centennial on October 9th.

A Case of Hydatid Tumor of the Brain—Removal—Recovery.—Drs. James Graham and C. P. B. Clubbe, of Sydney, Australia, report, in the *Australasian Medical Gazette*, July 15, 1890, the first successful case of operation for a cerebral hydatid tumor in that colony.

International Congress of Otology.—It has been determined to postpone the next meeting of the International Congress of Otology, which has been fixed to take place at Florence, in September, 1892, till 1893, when it will be held at Rome, a week before the assembling of the Eleventh International Medical Congress.

Medical Congress in Russia.—The fourth congress of the Society of Russian Medical Practitioners will be held at Moscow, the day of meeting being fixed for January 3, 1891. The work is to be done in twelve sections.

The Effect of Iced Tea.—Dr. G. W. Bar writes, in the *Therapeutic Gazette*, that iced tea has none of the physiological action of theine if it is kept ice-cold for a short time. He says that he has known a man of nervous temperament, who is kept awake all night by a single cup of tea, to drink a half-gallon of iced tea during the evening and sleep soundly at his usual time of retiring. Others, made very "nervous" by hot tea, have been able to drink large quantities of iced tea with no appreciable effect. If the tea-grounds are allowed to remain in the liquid, the iced tea is usually kept long enough before drinking to dissolve more tannin than is usual in hot tea; hence the tea should be strained as soon as removed from the fire. A correspondent sends us a note to the effect that he has found that iced tea will sometimes cause pruritus ani. Brown-Séquard has made a similar observation regarding coffee.

A Two-Hundred-Thousand-Dollar Libel Suit.—Suit has been entered by William Radam, manufacturer of Radam's Microbe Killer, against the *Druggists Circular*, of New York, for $200,000 damages, the largest amount, so far as heard from, that was ever asked for in a libel suit of this kind. The pleadings show that the action is brought to recover damages claimed to have been done the business of the plaintiff by an article published in the *Druggists' Circular* for September, 1889. This article gave the result of an analysis of the Microbe Killer, made by Dr. R. G. Eccles, a prominent chemist of Brooklyn, who stated that an identical preparation could be made by the following formula:

Oil of vitriol (impure)	4 drachms.
Muriatic acid (impure)	1 drachm.
Red wine, about	1 ounce.
Well or spring water	1 gallon.

This mixture, it was alleged, could be made at a cost of less than five cents per gallon, for which Radam charged three dollars. It was further alleged that while, when properly used, sulphuric acid, the principal constituent of the Microbe Killer, was a valuable medicine, it was, when taken without due caution or advice, a slow but certain accumulative poison; and the theories advanced by Radam, as to the causes of diseases and the proper method of treatment, were alleged to be totally erroneous. Colonel Robert G. Ingersoll, the famous lecturer, is the counsel for the plaintiff. The *Druggists' Circular*, which is published at 72 William Street, New York, expresses a desire to hear of any case in which unfavorable results have followed the administration of the Microbe Killer, or of any other fact that would be interesting under the circumstances. They claim to have published this analysis without malice, and with the sole intention of protecting the public from the loss of their health and money by the use of a dangerous nostrum.—*Boston Medical and Surgical Journal.*

Signor Jean Succi, the Italian faster and African explorer, has arrived in New York, and intends giving here another public exhibition of fasting. His last exhibition was at the Royal Aquarium in London, where he fasted for forty days and two and a half hours.

Koch's Remarks upon his Probable Cure for Tuberculosis.—"I have proved the following substances to be remedies which hinder the growth of tubercle bacilli in tube cultures (to mention only the most important): A number of ethereal oils; among the aromatic compounds, β napthylamin, paratoluidin xylidin; some of the so-called tar-dyes, namely, fuchsin, gentian, violet, methyl blue, chinolin yellow, aniline yellow, auramin; among the metals, mercury in the form of vapor, silver and gold compounds. The compounds of cyanogen and gold were especially conspicuous, their effect surpassing that of all other substances; even in a dilution of one to two millions they checked the growth of tubercle bacilli. All these substances, however, remained absolutely without effect if tried on tuberculous animals. In spite of this failure I have not allowed myself to be discouraged from prosecuting the search for growth-hindering remedies, and I have at last hit upon a substance which has the power of preventing the growth of tubercle bacilli, not only in a test-tube, but in the body of an animal. All experiments in tuberculosis are, as every one who has had experience of them has sufficiently discovered, of very long duration; my researches on this substance, therefore, although they have already occupied me for nearly a year, are not yet completed, and I can only say this much about them, that guinea-pigs, which, as is well known, are extraordinarily susceptible to tuberculosis, if exposed to the influence of this substance, cease to react to the inoculation of tuberculous virus, and that in guinea-pigs suffering from general tuberculosis, even to a high degree, the morbid process can be brought completely to a standstill, without the body being in any way injuriously affected. From these researches I, in the meantime, do not draw any further conclusions than that the possibility of rendering pathogenic bacteria in the living body harmless without injury to the latter, which has hitherto been justly doubted, has been thereby established."

A Tolerant Bronchus.—Dr. Lapeyre, of Paris, reports (*Lancet*) a remarkable case, in which an elderly gentleman, in consequence of a sudden slap on the back, unconsciously drew the cigarette he was smoking into his right bronchus, where it remained without causing any symptoms, or in any way revealing its presence for nearly two months, when it set up pneumonia of a circumscribed area, and produced cardiac weakness and some œdema of the legs. After this condition had lasted without much change for about two months more, the patient expelled, during a violent fit of coughing, the cigarette, enveloped in mucus and waxy-looking matter, and then remembered that he had never found his cigarette after the slap on the back four months before. The pneumonia persisted for two or three months after the expulsion of the foreign body, and some œdema of the right leg, due probably to embolism, remained at the date of the report, nearly a year later.

The Medical Department of the Brazilian Army is being reorganized. The officers and their ranks are as follows: One inspector-general (general), three first-class surgeons (colonels), nine second-class surgeons (lieutenant-colonels), twenty-seven third-class surgeons (majors), eighty-five fourth-class surgeons (captains), and seventy-five assistant surgeons (lieutenants). The pharmaceutical officers are: One first-class pharmacist (lieutenant-colonel), two second-class pharmacists (majors), eight third class pharmacists (captains), thirty-two fourth-class pharmacists (lieutenants), and forty-four assistant pharmacists (sub-lieutenants).

The New Medical Law of New Jersey.—Our medical friends in New Jersey, in their eagerness to prevent outside physicians from poaching on their preserves, may possibly find they have overstepped the limit of constitutional law. The old law, which was a very just one, required every physician, before he could practise outside his own State, to register his name, with the evidences of his authority to practise medicine, in the office of the county clerk. The new law, which went into effect July 4th, subjects every physician outside the State, except surgeons in the army and navy, to an examination before constituted authorities before he can prescribe even for his own patients who are sojourning for a time at the farm-houses or watering-places of New Jersey.—*New York Medical Times.*

Cremation at Milan.—Two systems of cremation are followed at Milan, by one of which the body is burned in a furnace surrounded by wood and charcoal, while by the other the combustion is brought about through a number of jets of gas which cast their heat upon the furnace from all sides. When wood and charcoal are employed about six hundred pounds of wood and one of charcoal are found necessary, and the process lasts two hours. When gas is used, all that is consumable in the body is burned up in less than fifty minutes. The body may, in ordinary cases, be introduced into the furnace with or without the coffin. But if death has been caused by some infectious disease the coffin and body must be burned together. The weight of the remains after cremation, in the form of bones and dust, is about four pounds. They are in color pure white, tinged here and there with a delicate pink; and it is a rule never to touch them with the hand. The bones and vestiges of bones (which are for the most part burned into powder) are taken up with silver tongs, while the ashes are removed from the furnace with a silver shovel, to be placed on a silver dish and then deposited in an urn for retention in the cinerarium. Here the ashes are preserved in separate compartments, each with a suitable inscription beneath it. The cost of cremation is $5 to a member of the Society for Extending Cremation in Italy, or $10 in the case of non-members.

The Prevention of Phthisis.—The announcement, almost simultaneously, of two methods of preventing the development of tuberculosis has apparently made very little stir in the medical world. The medical world, in fact, is getting apathetic on the subject of cures for phthisis. Still the present claims come from the two chief bacteriological laboratories of Germany and France respectively, and are put forth by Dr. R. Koch and by Dr. Grancher, both of whom are men to be trusted. Dr. Koch asserts, as we understand him, that he has found a chemical substance which, when given to animals, prevents the development of tuberculosis in them. Dr. Grancher has obtained by cultivation a fluid with which he vaccinates animals and thereby prevents also the subsequent development of tuberculosis.

Dr. Cosmo Brailly, of this city, died on October 5th, in the seventy-sixth year of his age. Dr. Brailly was born in France and graduated in medicine, in Paris, just fifty years ago. Dr. Brailly was author of a book called "The Destiny of Man."

Dr. Charles L. Hubbell died suddenly of heart disease on Tuesday in his room at the Taconic Inn, Williamstown, Mass. Dr. Hubbell was born in Williamstown in September, 1827. He graduated from Williams College in the Class of '46, and studied medicine at the Berkshire Medical College in Pittsfield, and also in New York. He went to the front in 1861 as surgeon of the Black Horse Cavalry, and served until the irregulars disbanded. He then entered the Twelfth New York Regiment as surgeon, and served until he was compelled by illness to resign, when he was made surgeon of the Board of Enrolment for the Army, and at the same time was appointed post surgeon at the Watervliet Arsenal, which place he held for twelve years. He was surgeon of the Marshall Infirmary, and connected with other hospitals and dispensaries in Troy until he went to Williamstown in 1885. He had been President of the Rensselaer County Medical Society, and was a member of the Berkshire and North Berkshire Medical Societies at the time of his death. He leaves five sons.

The Medical Society of the State of New York.—The Eighty fifth Annual Meeting will be held in the city of Albany, Tuesday, Wednesday, and Thursday, February 3, 4, and 5, 1891. The Business Committee has been appointed and is composed of the following-named gentlemen: Dr. Herman Bendell, 178 State Street, Albany, *Chairman;* Dr. Seneca D. Powell, 12 West Fortieth Street, New York; Dr. James D. Spencer, Watertown. It is desirable that all who intend to present papers shall send forward the titles thereof to any member of the Business Committee not later than December 15, 1890, as the programme will be made up and issued early in January.

Health Commandments.—We copy the following from the *Dixie Doctor*. It will strike the reader as being perhaps a little irreverent, and also as being rather more apodictic than exact in the field covered. For we are told not to eat pie, while nothing is said against whiskey. A large class of excellent people think that whiskey is less salutary than pie, but perhaps these people do not live in Dixie. "1. Thou shalt have no other food than at meal-time. 2. Thou shalt not make unto thee any pies, or put into pastry the likeness of anything that is in the heavens above or in the waters under the earth. Thou shalt not fall to eating it or trying to digest it. For the dyspepsia will be visited upon the children to the third and fourth generation of them that eat pie, and long life and vigor upon those that live prudently and keep the laws of health. 3. Remember thy bread to bake it well, for he will not be kept sound that eateth his bread as dough. 4. Thou shalt not indulge sorrow or borrow anxiety in vain. 5. Six days shalt thou wash and keep thyself clean, and the seventh thou shalt take a great bath, thou and thy son, and thy maid-servant, and the stranger that is within thy gates. For in six days man sweats and gathers filth and bacteria enough for disease; wherefore the Lord has blessed the bath-tub and hallowed it. 6. Thou shalt not smoke tobacco, for it is an abomination in the sight of all thoughtful men, and a mortal sin against thy Creator, who hast given thee a sound body and mind to be well preserved against such narcotic drugs. Remember thy sitting-room and bed-chamber to keep them ventilated, that thy days may be long in the land which the Lord thy God giveth thee. 7. Thou shalt not eat hot biscuits. 8. Thou shalt not eat thy meat fried. 9. Thou shalt not swallow thy food unchewed or highly spiced, or just before hard work or just after it. 10. Thou shalt not keep late hours in thy neighbor's house, nor with thy neighbor's wife, nor his man-servant, nor his cards, nor his glass, nor anything that is thy neighbor's."

A Country Doctor, being out for a day's shooting, took his errand boy to carry the game-bag. Entering a field of turnips, the dog pointed, and the boy, overjoyed at the prospect of his master's success, exclaimed, "Oh! master, there's a covey; if you get near 'em, won't you physic 'em!"—"Physic them! you young rascal. What do you mean?" said the doctor.—"Why, kill 'em, to be sure," replied the lad.

Obituary.

MONTROSE A. PALLEN, M.D.,

NEW YORK.

Dr. Montrose A. Pallen, of this city, died on October 1st, of heart disease, aged fifty-four. Dr. Pallen was born January 2, 1836, in Vicksburg, Miss. His father, a Virginian, was Professor of Obstetrics in the St. Louis Medical College for twenty-seven years. Dr. Pallen received his medical education at the St. Louis University, from which he was graduated in 1853. He studied medicine in the medical department of the same institution, and received his degree in March, 1856. He spent two years in the medical schools and hospitals of London, Paris, and Berlin, and then settled in St. Louis.

During the war Dr. Pallen was medical director of General Henry A. Wise's Legion in 1861, of General William J. Hardee's army corps in 1862, and later of the Department of Mississippi until February, 1863. Subsequently he was sent to Canada by the Confederate Government to report on the condition of the Confederate prisoners on Johnson's Island. He returned to Richmond in 1864, went to Paris, and obtained surgical and medical supplies for the Confederate armies. He was sent to Montreal again, but was captured on his way back to the South and held on parole in this city until the end of the war. He was Professor of Gynecology in the Humboldt Medical College in 1866–67, Adjunct Professor of Obstetrics in the St. Louis Medical College 1867–68, Professor of Gynecology in the St. Louis College of Physicians and Surgeons 1869–70; Professor of Anatomy in the Missouri Medical College, 1871–72; and Professor in the Medical Department of the University of the City of New York, 1874–82. In 1883 he assisted in forming the Post-Graduate Medical College in this city. He also served as surgeon to the Charity Hospital.

Dr. Pallen was widely known as a writer for medical periodicals, and published many articles on obstetrical and gynecological subjects. He was a member of the American Medical, and the New York Journal and Library Association, and of the New York County Medical, the New York Obstetrical, and the New York Neurological Society.

Society Reports.

AMERICAN GYNECOLOGICAL ASSOCIATION.

Fifteenth Annual Meeting, held in the Buffalo Library, Buffalo, N. Y., September 16, 17, and 18, 1890.

JOHN P. REYNOLDS, M D., OF BOSTON, PRESIDENT, IN THE CHAIR.

FIRST DAY, TUESDAY, SEPTEMBER 16TH.

Invited Guests.—After the roll-call, the following gentlemen were invited to take part in the proceedings of the Society, as invited guests: Dr. Roswell Park, Dr. Tremaine, Dr. Fredericks, and Dr. Mynter, of Buffalo; Dr. Keith, of Edinburgh; Dr. Buckmaster, of New York; Dr. Carpenter, of Cleveland; Dr. J. A. Temple, of Toronto, Canada; Dr. Robb, of Philadelphia; Dr. Rosebrugh, of Hamilton, Ontario.

The address of welcome was delivered by DR. ROSWELL PARK, of Buffalo, on behalf of the physicians of Buffalo.

Diagnosis, Pathology, and Treatment of Extra-Uterine Pregnancy.—The discussion was opened in a paper by DR. A. W. JOHNSTONE, of Cincinnati. He said that the amœboid state is the first picture in the life of all viviparous animals. Immersed in a proper nutrient fluid, all alike from the first segmentation go on to the formation of hypoblast, epiblast, and, later, the mesoblast. Up to a certain point, all that is required of the mother is to furnish the properly-conditioned nutrient fluid. In the lower animals this lymph can only be furnished during the "rut" and without it pregnancy is impossible. In the human being the "rut" is sempiternal, and pregnancy can occur at any time. The adenoid tissue which furnishes this lymph lines the uterine cavity and the fallopian tubes to their extremities. Strip off the cilia from the epithelium of the tube and you have a condition analogous to the uterine lining, a place for fecundation. Extra-uterine pregnancy does not occur with a normal genital tract. Various abnormal conditions may cause loss of the cilia, and leave a place to which the ovum can adhere. "How often can the diagnosis of ectopic pregnancy be made before rupture?" is the practical question. The patient does not, as a rule, consult her physician until the occurrence of pain, and every colicky pain means a giving way of some part of the tube. The bleeding does not usually become alarming until the second or third month. Extra-uterine pregnancy, when discovered, should be removed by abdominal section. Electrical treatment is dangerous in practice, wrong in principle, and disastrous in its final results.

Dr. Johnstone appeared sceptical in regard to the probability of such a condition as ovarian pregnancy. He claimed that the specimen which Dr. Mann presented, in 1888, was a dermoid cyst and not an ovarian fœtation as claimed by Dr. Mann.

Dr. Johnstone was followed by DR. MATTHEW D. MANN, of Buffalo, who said: The view that the union of the male and female elements takes place in the uterus is erroneous. In ectopic pregnancy the union must take place in the tube or beyond it, and most of these pregnancies are primarily tubal. There is no possible doubt as to the occurrence of ovarian pregnancies. The specimen exhibited by Dr. Mann, in 1888, was unquestionably one of ovarian fœtation, notwithstanding Dr. Johnstone's positive declaration to the contrary. Placental tissue is not found in dermoid cysts.

After rupture laparotomy is clearly indicated. Electricity is ordinarily of greatest value, for if the embryo be killed the danger of rupture is over.

The discussion was continued in a paper by DR. J. M. BALDY, of Philadelphia. He stated that his arguments would refer to tubal pregnancy in the earlier stages of that condition. He did not deny the possibility of an ovarian or abdominal pregnancy, but claimed that, in the earlier stages, a differential diagnosis is quite out of the question, the symptoms are the same.

Symptoms of Ectopic Pregnancy.—The following are the symptoms of ectopic pregnancy: 1. A spurious fluid, simulating menstruation, which is at first lighter and then darker in color than the normal discharge, and which contains clots and shreds. 2. Pain, intermittent in character, cramp-like, and becoming more severe and more frequent. It may be so severe as to cause syncope, and its situation is invariably low down in the pelvis. This pain, in connection with the pseudo-menstrual flow, is strongly suggestive of ectopic pregnancy. 3. Discharge of shreds of decidua, with or without clots. 4. General signs of pregnancy, gastric, etc. 5. An occasional cyst in connection with one uterine appendage. 6. The patient's belief as to whether she is or is not pregnant. 7. Occasional elevation of temperature and acceleration of pulse. 8. At the period of rupture great pain and collapse, and the general signs of internal hemorrhage.

Dr. Baldy stated that the following propositions were justified by his experience and that of others: I. In a certain proportion of cases the symptoms, until rupture has occurred, are entirely wanting, or of such dubious character as to in no wise warrant a diagnosis of ectopic pregnancy. II. In a certain (quite large) proportion of cases sufficient symptoms are present to more than warrant a diagnosis of extra-uterine pregnancy, such a pregnancy not being present. III. In a certain proportion of cases, in the early stages, the diagnosis of extra-uterine pregnancy is easy and unmistakable.

Dr. Baldy believes that many cases of ectopic pregnancy go on to a spontaneous cure; that in some other cases there is death of the embryo and subsequent partial or complete absorption of the resulting hæmatocele, embryo, and membranes.

Where diagnosis is certain, laparotomy is to be preferred to electrical treatment. The former advocates of electricity now seem to favor laparotomy.

Ruptured Tubal Pregnancy.—DR. CHARLES JEWETT, of Brooklyn, presented a report of a case of "Ruptured Tubal Pregnancy," with the notes of the post-mortem examination.

A paper entitled "Under what Conditions can Electricity be of Positive Service to the Gynecologist," by DR. ANDREW F. CURRIER, of New York, was read by title.

DR. A. J. C. SKENE, of Brooklyn, believed that it was highly important that a diagnosis should be made in all cases of extra-uterine pregnancy with equal certainty whether the treatment contemplated be that of electricity or laparotomy, in order that patients *in extremis* could be intelligently cared for. He hesitated somewhat in expressing his views in regard to the importance of diagnosis, a subject about which so much has been said, but stated that he was firmly convinced that extra-uterine pregnancy is as easily diagnosed as any known affection of the female pelvic organs—as pyosalpinx or ovarian cyst—if there be no complication of other pelvic disease. Of course, if the case is complicated like the one mentioned, where the anatomy of the pelvic organs undergoes an entire change, diagnosis will be more difficult, but that is true of affections of any part of the body. It is very true, however, that patients very often do not come to us until after rupture occurs, and then, of course, a diagnosis cannot be made.

The doctor referred to a case of pregnancy in one horn of a uterus bicornis, in which he had treated the patient for dysmenorrhœa, the pregnancy occurring subsequently. The sac was soft, fluctuating, and movable, and lay in the region of the right tube, and had every appearance of a tubal pregnancy, which he should have diagnosed as such had he not been familiar with the previous history of bilobed uterus. This condition of pregnancy in one horn of a bifid uterus he held to be the only one which could not be differentiated from tubal pregnancy with certainty,

and that, excluding this one condition, the diagnosis of ectopic gestation was as easy and certain as any other form of disease.

In regard to the treatment of these cases by electricity, the speaker expressed the regret that such an important subject should have been so heatedly and doubtfully discussed, and that it should have received such merciless condemnation from the advocates of laparotomy, and believed that such acrimonious discussion between the electricians and laparotomists would never lead to the determining of the true value of either method of treatment, and he hoped there would soon be an end to it. He had seen no evidence that electricity was especially dangerous, and believed that it could be employed with entire safety, and failing to cure did not prejudice in the least the resort to the more conservative method of laparotomy. The laparotomists say that their operation must be done by "competent hands." Considering that the cases for laparotomy are emergency cases, perhaps if they examined the histories of the cases that have been operated upon by presumably "competent hands," they would not be so ready to condemn electricity.

Dr. W. W. Jaggard, of Chicago, thought Dr. Johnstone's statement in regard to the spermatozoa determining the site of the fecundated ovum did not throw any light on the general point of fecundation; and that to attribute the cause of labor to the cessation of the influence of the spermatozoa was carrying the action of the ferment a little too far. He was sure ovarian pregnancy had been definitively proved, and was not a discussable point, and that it was useless to discuss the case referred to by Dr. Mann, as the presence of decidua and villi had not been demonstrated microscopically. He thought it looked like a tubal pregnancy rather than a dermoid cyst, but did not think it wise to take cognizance of the observations of an unfamiliar observer in a case of this kind. Many things look like and are called fœtuses that are not fœtuses.

The speaker called attention to the fact that a great many cases of so-called tubal pregnancy are simply hæmatoma of the tubes, and that many cases of hæmatosalpinx are really tubal pregnancies.

Dr. A. Kellar reported several cases in which villi of the chorion were found in these blood-tumors of the tubes. The natural history of tubal pregnancy has three terminations: 1, Death before rupture; 2, rupture; 3, going on to term. When the tube ruptures, the following subterminations may be observed: 1, Rupture into the broad ligament with formation of hæmatoma of broad ligament, favorable termination; 2, after rupture ovum may remain in situ and plug it up, acting as a tampon, favorable termination; 3, it may rupture with formation of retro-uterine hæmatocele, favorable termination; 4, rupture into the abdomen with intra-peritoneal hemorrhage. With the exception of the last, all of these are favorable terminations, and, as a rule, ruptured tubal pregnancy will recover, if left alone.

He agreed perfectly with Dr. Skene in regard to diagnosis being easy in uncomplicated cases. And cited a typical case of tubal pregnancy (seen recently with Dr. Bonner, of Chicago) diagnosed and operated on before rupture, with removal of fœtus intact, the patient making good recovery. The points in the diagnosis were: Slight bluish discoloration of the anterior vaginal wall, softening and compressibility of the lower uterine segment (Hegar's sign); uterus displaced to the left, retroflexed, enlarged, and of a peculiar, soft, doughy consistency; to the right of the median line a well-marked small, almond-shaped, non-fluctuating tumor, resembling somewhat an ovarian cyst. This woman was thirty years old, and had three children; two were born at regular intervals of about two years, and there was an interval of three years between the third and fourth pregnancies, which latter was on the right side, and it should be noted that the typical cases of extra-uterine pregnancy occur in old multiparæ going a long interval between pregnancies, or in primiparæ who have been sterile for a long time.

The evidence in favor of laparotomy, where diagnosis is made before rupture, is conclusive.

Dr. Veit's article on the diagnosis and treatment of early tubal pregnancies, including some ten cases diagnosed before rupture and operated upon with but one death, was referred to as being the best result obtained by any method of treatment.

He makes the following objections to the use of electricity: 1, Danger of rupturing the sac; 2, uncertainty in diagnosis; 3, after the eighth week it is hopeless to expect resorption of the fœtus or placenta. He agrees, however, with Dr. Skene, that it is well to be temperate in the condemnation of electricity.

The universal proposition that every case of ruptured tubal pregnancy is an indication for laparotomy is an erroneous one, and has proved most disastrous in practice. The principal indication for laparotomy is where there is a free intraperitoneal hemorrhage. In the event of hæmatoma of the broad ligament, broad ligament pregnancy, rupture of the tube, the clot acting as a tampon, the indications are all strongly against laparotomy.

Dr. H. P. C. Wilson, of Baltimore, was entirely in accord with Dr. Skene. He believes extra-uterine pregnancy is very frequent, but that ovarian pregnancy is very rarely met with; that if ectopic pregnancy can be diagnosed in its early stages electricity is the proper treatment. He would adopt three months as the limitation for the application of electricity to destroy the fœtus, rather than four months, as advised by Dr. Mann, and has succeeded a number of times in destroying the fœtus before the end of the third month. Failing in that he would resort to surgical measures, which he estimates to be fully as valuable under the proper indications as electricity. In the early stages of ectopic pregnancy the women are usually in good health and cannot believe that such a serious thing as cutting into the abdomen is necessary, and you can rarely get their consent to such a procedure, hence the resort to electricity. In hospital cases you may operate at the beginning, but not in the better class of patients. Should the case, however, go on beyond three months, to cut in and remove the fœtus is the manifest duty of the gynecologist.

Dr. Howard A. Kelly, of Baltimore, referred to Mauriceau's case of extra-uterine pregnancy in 1669, described as follows: "History of a woman in whose abdomen there was found, after death, a small fœtus about two and one-half inches long, together with a great quantity of coagulated blood." The woman had borne eleven children at term but in the twelfth pregnancy at two and one-half months the uterus dilated in the direction of the right horn and ruptured. It was thought by many to be a true tubal pregnancy, and cited as an instance of retention of an ova in the tube, becoming fecundated, and subsequently going on to gestation within the tube, and final rupture. Mauriceau called it a hernia from the uterine body proper, and was much opposed to its being called a tubal pregnancy, which it was not. It was plainly a case of pregnancy in a rudimentary cornu uteri, demonstrated by a small bridge of tissue between the fœtal sac and the uterus; decidedly not a tubal pregnancy, because the round ligament of the right side was displaced downward.

In the last century there was much excellent work done in this direction. The best plates ever published on abdominal extra uterine pregnancy, were by Deutsch, in 1792, showing the fœtus life-size in the belly of the mother attached by the cord to the placenta which is implanted low down in the abdominal cavity.

The speaker believed it was possible to recognize the following forms of extra-uterine pregnancy. 1, Interstitial; 2, tubal; 3, tubo-ovarian (doubtful); 4, ovarian, proven beyond a doubt by the cases of Gottschalk, in the *Centralblatt*, 1886, Patenko, Leopold, and Spiedelberg; 5, primary abdominal, remaining to be proved. The

tubal may be divided into: *a*, Isthmial; *b*, isthmio-ampullar; *c*, ampullar, according to their relative position in the tube.

The critique of ovarian pregnancy: An extra uterine fœtal sac, which must have the same relation to the uterus as the ovary maintains; the tube must remain intact, and the ovarian ligament connecting the side of the sac with the uterus must be present. The ovarian ligament is as important to the establishing of ovarian pregnancy as the round ligament is to that of interstitial pregnancy.

In a case five months beyond term, recently operated upon in the Johns Hopkins Hospital by Dr. Robb, which proved beyond question to be an unruptured tubal pregnancy, ovarian tissue was present in the sac-wall, which goes to show that the mere evidence of ovarian tissue in the walls of the sac is not conclusive of ovarian pregnancy.

It is interesting to note how the men who claimed no diagnosis could be made have shifted their ground since so many positive diagnoses have been made, and now say that diagnosis cannot be made before rupture. Very few cases are seen before rupture, but the following case was diagnosed by the speaker, and seen by Dr. Robb, before rupture, and operated upon with removal of the unruptured sac. Mrs. B——, been married three years, aged twenty-two, had had one child and one premature stillbirth. Came under observation early in December, 1885. Had menstruated regularly up to July previous, but from that time to the middle of November she had not menstruated. Menstruation began again in the middle of November with the discharge of "a piece of flesh," as she termed it, and with the re-establishment of menstruation she was relieved of severe pain arising from a lump low down on the right side which she had suffered constantly from since early in October. First examination showed a very smooth, tense, elongate tumor, anterior to the cervix, lying far back in the sacral hollow; could be easily felt over the whole extent of the anterior vaginal wall, extending above half-way to the umbilicus, presenting peculiar tense fluctuant feeling. Uterus small and retroposed, reclining in the hollow of the sacrum.

At her next visit she thought herself pregnant. The uterus could not be felt so clearly and the case presented the appearance of extreme anteflexion of a pregnant uterus. After this she had several bloody discharges up to March 8th, when she had regular flow for five days.

At this time tense ovoid cyst could be felt through the anterior vaginal wall, on the right side, its axis in the plane of superior strait, anterior extremity at symphysis pubis to the right, posterior extremity at right cornu uteri; connected by short pedicle to the uterus; sensitive, smooth, and had remarkable rubber-ball, elastic feeling; much tenderness low down on left side, where there is an indistinct worm feeling about the retroposed cornu uteri. The tumor had diminished remarkably in size while under observation. Diagnosis of extra-uterine pregnancy positively made and operation performed in the presence of five other gentlemen.

In these cases it is always best to assume that the worst condition is present until by proof it is excluded.

The most recent case in which diagnosis was correctly made before operation was in the practice of the speaker at the Johns Hopkins Hospital, before thirty-two witnesses; confirmed by operation, removing well-developed fœtus from the abdominal cavity, where it had escaped from a ruptured tube. Diagnosis can be positively made if the following symptoms are present: 1, Cessation of menstruation followed by irregular recurrence; 2, pain in the lower part of the abdomen; 3, fluctuating tumor; 4, enlarged uterus (not always present); 5, discharge of membrane, which is very characteristic; 6, milk in the breasts; 7, tumor diminishing in size under observation —a pathognomonic sign, rarely present unless electricity be used, which, of course, implies death of the fœtus. There is another class of doubtful cases where some of the symptoms are present, and still another class of uncertain cases where there are no signs and which are generally discovered accidentally. If he finds a freely movable tumor in the abdomen he would perform laparotomy, but if the tumor has ruptured into the broad ligament he would use electricity and wait for results up to the end of the third month.

He would not consider the life of the fœtus to the detriment of the life of the mother, but consider the fœtus simply as a malignant foreign body. If he had a living fœtus at term he would open the abdomen, and if it prove to be an unruptured tube, with the placenta enucleated in the sac, the latter could be removed and the life of the fœtus saved. If the placenta were attached to the intestines he would remove the fœtus and drop the funis back into the abdominal cavity, and later perform laparotomy if necessary.

Dr. Hunter Robb, of Philadelphia, believed that the tubes were the most frequent site of fecundation, that ovarian pregnancies do take place, and agreed with Dr. Jaggard that microscopical examination is alone reliable in determining this condition.

He believed the diagnosis was as easy as that of fibroid or parovarian cyst. He corroborated Dr. Kelly's cases.

Dr. Joseph Taber Johnston, of Washington, remarked that the paper of Dr. Hanks, read before the Society in 1888, gives the history of eleven cases, with the statement that diagnosis ought to be possible in ninety or ninety-five per cent. of all cases; that he believes in electricity in the beginning and operation afterward if necessary. He thinks electricity will kill the fœtus and that in all cases of rupture the operation should be done at once.

Dr. A. N. Buckmaster, of Brooklyn, thought it would be a fatal blow to the use of electricity in these cases if it should be proved that it could not accomplish the destruction of the fœtus. In reply to Dr. Baldy's accusation, that he had with twenty milliampères failed to kill the fœtus, he said that there was a large fibroid tumor present, through which the current passed, and that very little could reach the fœtus in utero; that it is unfair to assume that because the current applied at a point outside the fœtus in the uterus failed to kill, that it would not destroy the fœtus in the tube, and that it was not a case to be quoted against the use of electricity.

Dr. J. A. Temple, of Toronto, related a case of extra-uterine gestation in which he operated and removed the tumor and tube without rupture. Patient made good recovery and stitches were taken out on the sixth day. On the eighth day she had a severe attack of mania and talked incessantly day and night for three days, resisting all methods of treatment. On the twelfth day she became semi-comatose, did not recover consciousness, and died on the twenty-third day, perfectly insensible. Passed abundance of urine which showed no traces of albumin, no symptoms of paralysis present. Fed with stomach-pump for eleven days. He was confident the patient did not die from septicæmia or other similar affection, as the result of the operation, which he believed was a case which had every indication for such a procedure, but that she died from some unknown cause. No autopsy could be obtained.

Dr. Matthew D. Mann, of Buffalo, reiterated the views expressed in his paper in regard to the specimen which he presented two years ago, and, notwithstanding Dr. Johnstone's doubts of its genuineness, he still held it to be a true ovarian pregnancy. His opinion in regard to the use of electricity in properly selected cases was also unchanged.

Dr. A. W. Johnstone, of Cincinnati, doubted the existence of ovarian pregnancy, and believed he had never seen a true case. He believed the electrical treatment subjected the patient to all the recurrent evils of pelvic disease, and the only safe method was to cut in and clear everything away without delay.

Question of Amperage in the Treatment of Fibroid Tumors by Electricity.—Dr. W. C. Ford, of Utica, read

a paper on the above subject. Myomatous growths are easily managed by galvanism. They are of comparatively low resistance, a very large and hard one offering but 300 ohms. The question has been asked, "What happens when the current passes through a fibroid mass?" Simply the separation of the fluids in this mass and their reformation into different chemical combinations which interfere with the intra-uterine existence of the growth. This is merely a process of electrolysis. The current necessary to produce this electrolysis is not one of tension, but of volume or quantity, and this depends entirely on the cell which is used. The small bichromate of potash battery with a single plate of zinc and carbon, which we find so much in use, unless a very large number of cells are employed, does not give sufficient volume—has not sufficient amperage—to effect the necessary electrolysis, but by using a larger cell, having a zinc plate between two good-sized carbon plates, say seven by two, we get a greater surface exposed for chemical action and hence a greater volume, or amperage, of current, which affords sufficient electrolytic action to decompose the fluids of the fibroid tumor and arrest its growth; but with high tension and low amperage, as in the small-cell battery, this result cannot be accomplished without employing a great number of cells. The latter has an electro-chemical or cauterizing action, while the former produces simple electrolysis.

He uses the negative or active electrode in the uterus, and the positive electrode externally over the abdominal wall. His uterine electrode consists of a pure platinum needle with a blunt end, like Apostoli's needle. He has also used the gas carbon electrode. For an abdominal electrode a plate of copper, covered with punk, is substituted for Apostoli's clay electrode. The plates are of all sizes.

The fluids of the tumor decompose at the internal negative electrode and bubble up and run out over the electrode in sufficient quantity to be caught in a spoon speculum after a few minutes' application, if the current have the proper amperage. The author has accomplished this with a battery of fifteen of the large bichromate of potash cells referred to. The fluid of the tumor has an intense chlorine smell and is strongly alkaline The current is well distributed by the abdominal electrode, and there is no risk of blistering the abdomen as there is absolutely no cauterization produced.

The author was convinced that the cure of these fibroids by electricity could be brought about in no other way than by having a sufficient *volume* of electricity carried by the electrode to produce perfect electrolysis.

Dr. Tremaine, of Buffalo, after an experience of sixteen cases, was disappointed with electrical treatment. He questioned why the current which decomposed the tumor did not have the same effect on the abdominal walls and intervening tissues.

Dr. A. J. C. Skene, of Brooklyn, replied that the tumor, being of low vitality, was decomposed, while the normal intervening tissues, being of a higher vitality, resisted electrolysis. He would avoid cauterization, as it is not necessary to stop the growth of the tumor. The positive pole in the uterus produces stenosis, which can be avoided by using the negative pole. He would limit the word "cure" to mean an arrest of growth, and in that sense there were many cures.

Dr. H. P. C. Wilson, of Baltimore, preferred the carbon uterine electrode to the platinum for bleeding myoma. He would not use electricity in intra uterine pediculated myoma or sub-peritoneal pediculated myoma, or soft œdematous myoma, but in the intra-mural he believed electricity would cure.

Dr. Mynter, of Buffalo, thought the diversity of opinion in regard to electricity due to the fact that many operators used a battery producing an electro-chemical or cautery effect, instead of one producing electrolysis, and that electro-chemical action frequently caused sloughing.

Dr. George Keith, of Edinburgh, believed it most important to first make a correct diagnosis, and then treat.

Dr. Rosebrugh, of Hamilton, Ont., asked whether any ergot or other medication was given in addition to the electricity.

Dr. Wilson considered ergot worthless. He used bromide of potash to regulate the nervous system, and kept the bowels regulated.

Dr. Ford never found soft œdematous fibroids unyielding to electricity, but in very hard ones he had found it necessary to cauterize.

Dr. Gehrung, of St. Louis, was in favor of puncture and electrolysis, using trocar electrode and double cannula with tubes attached, so that if the fibroid is a cystic one the aspirator can be applied and the cyst cavities washed out.

Dr. Skene in cases of bleeding fibroid would remove a portion of the hypertrophic uterine mucous membrane, and apply iodine to the membrane as a disinfectant. In severe hemorrhage he thought hydrastis canadensis was the best disinfectant and had a salutary effect on the uterine mucous membrane.

Second Day, Wednesday, September 17th.

Vaginal Fixation of the Stump in Abdominal Hysterectomy was the title of a paper by Dr. Henry T. Byford, of Chicago. Extended experience had taught the writer the advisability of modifying his former method of operating. He now separates the bladder from the cervix, cuts and tears down through the anterior vaginal wall, anteverts the stump into the vagina, holding it there by tenaculum forceps. The peritoneal cavity is closed by suturing the reflected edge of the bladder peritoneum to the posterior surface of the stump with catgut. The use of the elastic ligature on the stump is most important.

Dr. Byford reported eight cases, and in only one of these was the result unsatisfactory, and in this fatal case the operation was not at fault.

Dr. Howard Kelly, of Baltimore, divided fibroids into four classes: 1. Pediculated intra-uterine, which can be removed through the cervix; 2, those which can be removed through the abdominal incision by myomectomy without removing any substantial portion of the uterus; 3, distinctly pediculated, which can be removed by supravaginal hysterectomy; 4, atypical cases, spreading out laterally in the broad ligament, non-pediculated, usually followed by death from hemorrhage and shock.

The ligation of a pedicle controls hemorrhage for the time being, but it may become a source of contamination after it is dropped back into the abdominal cavity by a recurrence of the hemorrhage.

He considered Hegar's method of allowing the stump to slough off as unsurgical a procedure as to tie a string to the finger and allow it to slough off. His plan is to suture the stump with buried and superficial sutures and suspend it in the lower angle of the abdominal incision. He has done this nine times with but one death, which was due to vascular lesions. He believes Byford's method of vaginal fixation is more specially adapted to small tumors, and that he would have difficulty in dealing with a broad pedicle; but it has the advantage over his own method of avoiding the risk of hernia following suspension of the stump in the abdominal incision, and by its dependent position also affords excellent drainage.

Dr. William M. Polk, of New York, would treat the large non pediculated tumors spreading out in the broad ligament by a process of complete enucleation, ligate the uterine artery, and, in case there was profuse hemorrhage from the posterior wall of the tumor, would ligate the utero sacral ligaments. The cervical canal is thoroughly cauterized and the iodoform packing brought out through the abdominal incision.

Dr. E. C. Dudley, of Chicago, had twice successfully performed Byford's operation, with a simple modification in the iodoform packing.

Dr. Skene thought Byford's method only applicable where the stump is small. He believed complete removal of the cervix, or dilation of the cervix and complete inversion of the same, might be substituted for Byford's operation.

Dr. Joseph Taber Johnson, of Washington, had successfully performed Bantock's operation in five cases. He preferred a long convalescence, due to the sloughing off of the stump in this operation, to some other operation without recovery. Complete removal of the infected stump, with proper drainage, he thought would be the ideal method.

Dr. E. C. Dudley had found inversion of the stump almost impossible to accomplish. He considered the entire removal of the stump, with vaginal clamp, a very difficult, and not very practicable operation. Byford's method should be employed in all cases of large fibromata which completely fill the uterus and spread out into the broad ligament. The vagina will hold quite a large stump.

Dr. George Keith, of Edinburgh, stated that his father had not given up hysterectomy, but that he always resorted to it if electricity previously applied proved unsuccessful.

Dr. Polk thought this was encouraging to those who held the same views as the elder Keith. He agreed with Dr. Dudley in regard to complete removal of the uterus and cervix, with clamps in the vagina to control hemorrhage, and considered it inferior to complete extirpation of the uterus with the use of the ligature. Byford's method has the advantage of simplifying and shortening the operation.

Dr. Howard Kelly believed there was a certain class of cases in which the hemorrhage could not be controlled by the methods discussed. He exhibited a corrugated uterine sound which he had devised by which he could locate the uterine arteries when they were displaced, and thus control hemorrhage. In cases of excessive hemorrhage he would tie the ovarian veins and arteries up into the abdominal cavity, and in desperate cases, where it was impossible to remove the tumor, he would adopt the heroic treatment of temporarily compressing the abdominal aorta. He considered Bantock's operation as only fitted for cases of pediculated fibroids, and if applied exclusively to such cases the mortality should be nil.

Dr. J. C. Temple, of Toronto, thought total extirpation of the entire mass the most rational procedure, and that inversion of the mass through the dilated cervix was attended with the greatest difficulty. He believed Byford's method a good one in selected cases where the whole of the tumor was not to be removed.

Dr. Byford closed the discussion.

Injuries to the Ureters During Labor, was the title of a paper by Dr. A. J. C. Skene, of Brooklyn. He believes that many symptoms following labor are due to injury to the ureters. The discharge of blood and pus, in from three to five days after labor, may be caused by blocking up of the ureters on account of a pressure from the head of the child, or other conditions which may produce partial or complete closure. Acute disease of the kidneys may occur secondarily. The diagnosis of injury to the ureters must be made by excluding the ordinary puerperal affections. The natural tendency is toward recovery, but uræmia due to disease of the kidneys may prove fatal.

The following is a convenient classification of diseases and injuries to the ureters: 1, Injuries of the ureters during labor; 2, obstructions of the ureters secondary to other pelvic inflammations; 3, obstructions due to neoplasms and uterine displacements. The second and third are taken from Englemann.

The conditions which predispose to injury of the ureters are: the bladder and terminal ends of the ureters resting low in the pelvis toward the end of gestation; defective nutrition of the ureters with a consequent loss of elasticity and resisting power; pre-existing lesion or functional derangement of the ureters.

The prevention of injury to the ureters is of greatest importance. The recognition of disease before parturition will oftimes save much trouble. Free dilatation of the cervix, before rupture, insures comparative safety.

Treatment must be in a great measure expectant. Surgical treatment of these affections is not in a highly developed state.

Incontinence of Urine Due to Malposition of the Ureter, by Dr. F. H. Davenport, of Boston, was the report of a case in which a woman, twenty nine years of age, had suffered with incontinence of urine all her life. A careful examination showed that one ureter emptied near the meatus instead of at the usual place. An operation was performed, which had for its object the establishment of an opening into the bladder, by transposition of the ureter. The operation was not a complete success, but a second operation was thoroughly satisfactory.

Dr. W. W. Jaggard, of Chicago, thought that injuries to the ureters were quite common during pregnancy, but not common during labor, during which the bladder is drawn up and becomes an abdominal viscus, and the ureters are not exposed to pressure from the head of the child, and that they are rarely injured by the dilatation of the cervix or use of the forceps before the engagement of the head. Compression or dilatation of the ureters has been recognized as a principal causative element in eclampsia, the speaker having seen one such case.

Among the specially operative causes of injury to the ureters during pregnancy he mentioned increased abdominal tension, presence of small ureteral calculi, calcareous pyelitis, having seen two cases where calculi were the probable cause of a dilated ureter. He considered palpation of the ureters during the puerperium as an unnecessary and extremely hazardous proceeding.

Dr. A. W. Johnstone, of Cincinnati, related a fatal case of injury to the ureter following a laparatomy for ovarian cyst in which furious mania was developed within forty eight hours. Where the ureter passed over the pelvic brim it was pressed upon by the tumor, developing purulent inflammation in the ureter, the kidney also being disorganized. Many cases of mania following laparotomy he believes to be due to some such condition as this.

General tuberculosis is a frequent condition of the ureters. A case was mentioned where the bladder, ureters, and kidneys were found studded with miliary tuberculosis.

Dr. Henry T. Byford, of Chicago, believed that uræmic convulsions due to ureteral injury was a frequent cause of death in pelvic disease, though many times death was attributed by the general practitioner to the primary pelvic disease which caused the ureteral trouble. He considered catheterization of the ureter difficult, but quite possible to perform.

Is the Mortality after Gynecological Operations Affected by Climatic Influences? by Dr. Henry C. Coe, of New York.—The writer, after much search and inquiry, had been led to believe that climatic change or season had nothing to do with mortality after gynecological operation. His conclusions were based on extended hospital and private practice, occurring in his own experience and that of others.

Cephalhæmatoma.—Dr. Howard A. Kelly, of Baltimore, read a paper with the above title. The writer stated that this affection is rarely recognized by the general practitioner. It occurs once in about every two hundred and fifty obstetric cases and runs a well-defined course. The following is a brief description of the lesion: Cephalhæmatoma is a circumscribed effusion of blood between the periosteum and one of the flat cranial bones, appearing usually the day after birth, and gradually increasing in size until it forms a tense rounded or ovoid prominent swelling. Its commonest seat is over one or both parietal bones, but it never crosses a suture. The skin over the tumor remains movable and unaltered in appearance, and the tumor itself is not painful nor does it de-

crease in size upon pressure. As a rule, it gradually disappears by absorption in two or three weeks. One more important diagnostic sign is the existence of a circumferential bony wall, which can be distinctly felt and which gives one an impression of a depressed fracture. The collection of blood may be absorbed or it may undergo suppuration. It is wise to wait two or three weeks, and, if absorption does not take place, incise the tumor, empty it, and use antiseptic dressings.

DR. W. W. JAGGARD, of Chicago, believes external cephalhæmatoma occurs in many labors, attracts, practically, no attention, and is healed spontaneously. The internal variety frequently causes strabismus and death. He thinks they always occur from injury during labor, from the stretching downward of the periosteum and rupture of its vessels, or approximation of the bones of the fœtal head by the forceps. In the aftercoming head and transverse presentations it is nearly as frequent as when the vertex presents.

DR. FREDERICKS, of Buffalo, reported two fatal cases of cephalhæmatoma, the children dying of convulsions, and a third case, in which the tumor at the end of six weeks had entirely disappeared.

DR. KELLY was sure these tumors were not of traumatic origin during labor, and were most frequently observed after easy and simple labors. He believes they originate from some predisposing cause, as they have been detected on the child's head before birth, on the head of a six months' fœtus, and in one case on the head of a child born by Cæsarean section.

Drainage after Laparotomy, by DR. THOMAS A. ASHBY, of Baltimore.—The writer stated that two accidental experiences had led him to adopt drainage after laparotomy. He believes that this method is the safest and surest, that it reduces the temperature, the tympanites and the gastric disturbances. He recommended that the abdominal cavity be washed out every four or six hours, and that the glass tube be left *in situ* for two or three days, and, afterward, a rubber tube made to replace it.

DR. A. PALMER DUDLEY, of New York, said, out of a series of 79 abdominal sections 69 were made without any drainage-tube, and without a death, although there was a large quantity of fluid in many of them. He would only use the drainage-tube under two conditions—where there is general peritonitis and hemorrhage is suspected, and where the peritoneum is congested from a recent peritonitis and bleeds if irritated with a sponge. The proper toilet of the peritoneal cavity before closing the abdomen will, under all other conditions, give better results. When life is endangered by grave septic inflammation in the pelvic cavity, the drainage-tube is useless, soon becoming walled in by the collection of lymph around it. The dangers of using it are from intestinal adhesions, fecal fistula, and occasional hernia. He believes the intestinal tract is the best drainage tube, and by giving saline cathartics just before operation it affords ample drainage, especially if there be intestinal fistula. He uses the catgut suture.

DR. E. C. DUDLEY, of Chicago, believed the system of drainage devised by Michaelis, of packing the area to be drained with iodoform gauze, was the best in all bad cases where there was a large surface to be drained, and that the frequent mistake was in removing the gauze too soon.

DR. M. D. MANN, of Buffalo, never used the drainage-tube where it was possible to do without it, and always felt uneasy while it was in. He would reverse the rule, "When you are in doubt, drain," and say, "When you are in doubt, wait." Don't close the abdomen too quickly; wash out the cavity with hot water, and frequently the hemorrhage will cease and the abdomen can be closed without drainage. He believes in drainage by the intestines and general system, and by starving his patients for forty-eight hours deprives the system of fluids and makes a great call on the lymphatics, which will take up the effused serum from the abdomen better than any drainage-tube.

THIRD DAY, THURSDAY, SEPTEMBER 18TH.

The Comparative Value of the Biniodide and the Bichloride of Mercury as Surgical Antiseptics, by DR. CHARLES JEWETT, of Brooklyn.—The biniodide of mercury, if used in proper concentration, is as potent in its germicidal properties as the bichloride. It is less unstable as a chemical compound, is more agreeable to the operator, and it is less toxic. Experiments made at the Hoagland laboratory justified the following conclusions: 1. In equal concentration the biniodide is slightly inferior to the bichloride in germicidal power. 2. The difference in the efficacy of a 1 to 1,000 and a 1 to 2,000 bichloride solution is insignificant. 3. The activity of a 1 to 2,000 biniodide solution is materially greater than that of a 1 to 4,000 solution. 4. For equal potency as a sterilizing agent the biniodide should be used in a more concentrated solution, say 1 to 1,800. The use of alcohol before the sterilizing solution, by its hygroscopic action, gives a better result.

DRS. W. L. RICHARDSON and A. D. SINCLAIR, of Boston, presented a tabulated report of measurements of the uterine cavity after childbirth.

A Report of My Recent Experience in Restoring Lacerations of the Sphincter Ani by the Flap-Splitting Process.—DR. HORACE TRACEY HANKS, of New York, read a paper on the above subject. The many slightly different operations for restoring lacerations of the perineum have been followed by fairly good results when performed by wise surgeons. The after-treatment of keeping the bowels open for ten days, as recommended by the writer, offers a decided advantage. Tait's operation is the best, and it is the most quickly and most easily performed.

Dr. Hanks cited five successive cases in which the results were perfect. He has modified Tait's operation in some respects, and the following is the method of procedure: The bowels must be moved freely for several days before the operation, and an enema given the morning before operating; the patient is put in the lithotomy position, and the vagina and rectum washed out with a 1 to 4,000 bichloride solution; the upper rectal pouch is filled with cotton balls which have been soaked in an antiseptic solution. The first incision is made just below the torn sphincter, on the patient's left, and the rectum is split from the vagina, from the sphincter up to the angle of the tear in the recto-vaginal septum, and it is then split at the angle for fully half an inch. These steps are repeated on the opposite side. After the parts have been properly irrigated, the vertical incisions are made, and the tissues under the triangular flaps dissected. The sutures are then put in place, beginning below the level of the anus. The bowels must be kept freely open from the second day. The sutures may be removed after ten or twelve days.

DR. E. C. DUDLEY believed no particular operation could be laid down for all cases. He considered it most important to restore the rectal side of the rent. He does not believe the size of the perineal body has so much to do with its efficacy as its location. If it is small and located well up, hugging the pubes, it is all right, but if it be located down toward the tip of the coccyx and relaxed, be it ever so large, it will not perform its functions, and operation on the vaginal outlet is quite as important as if the perineal body had been lacerated.

DR. POLK, of New York, thought the most important factor was the levator ani muscle, which if it is not relaxed and is well up near the pubic bone pulls the posterior wall of the vagina with it, which consequently catches the pelvic pressure.

DR. DUDLEY, of Chicago, modified Emmet's method of suturing, and instead of placing all the sutures at one time and tying them afterward, he tied each suture as it was introduced and made upward traction on the free ends, thus bringing the perineum well up against the pubic bone.

Laparotomy for Intrapelvic Pain. — A paper with the above title was read by Dr. Thomas A. Ashby, of Baltimore. Intrapelvic pain is associated with a number of intrapelvic conditions of structural, inflammatory, and neuralgic origin. The severity of the pain bears no appreciable relation to the magnitude of the intrapelvic condition. Pain, as a symptom, may be considered to stand alone, and not to depend upon lesions which can be recognized by the usual methods of diagnosis. Many cases of ovarian neuralgia cannot be cured before the menopause, unless operation be resorted to. Palliative treatment is useless, and laparotomy is warranted. In addition to neuralgia, there is a distinct class of lesions which involve the pelvic organs, and produce intrapelvic pain of a severe character. These lesions cannot be recognized, except by an exploratory operation. Minor displacements, chronic inflammations, and vascular disturbances may be classed among these. The surgeon is at fault if he fails to resort to operation where no other method of treatment offers any hope of giving relief or of making a diagnosis.

Dr. Howard Kelly strongly condemned the performing of laparotomy for pain, the admission of which would lead to the practice of former years, of performing laparotomy for almost every known disease. He believes oöphoralgia is rarely heard of, the condition which characterizes it generally arising from some other disease of the organ. Ovarian troubles can always be diagnosed by birectal or bivaginal examination under an anæsthetic. Radical measures should not be resorted to until all other forms of treatment have failed.

Dr. A. Palmer Dudley, of New York, was in favor of laparotomy for the relief of conditions which produced pain after the failure of all other methods of treatment. Vascular disturbance he believed to be the foundation of all pelvic diseases in the female. The pressure of the sigmoid flexure of the colon and the transverse circulation of the kidney upon the ovarian veins sometimes causes varicocele, which has been noticed by Skene, Polk, Lusk, Currier, and Neilson, as well as the speaker. Subacute inflammation and formation of adhesions is also produced by this pressure on the ovarian veins, which can only be broken up by a laparotomy. He reported three cases where, after exhaustive palliative treatment, he had performed laparotomy, drained the cysts found in the ovary, allowed them to refill with blood, and then returned them to the abdominal cavity, with immediate relief of the pain and rapid convalescence.

Dr. Polk, thought an exploratory incision entirely justifiable; and that birectal or bivaginal touch would not in all cases reveal the diseased condition of the ovaries. He believed complete amputation of the ovary could be avoided by cutting it open to discover the trouble, then sewing it up and returning it; also that catarrhal salpingitis does not justify amputation.

Dr. Byford, of Chicago, believed if the ovary is cut with a knife or suture, adhesions would form which might subsequently necessitate its entire removal.

Dr. M. D. Mann approved of an exploratory incision as a means of diagnosis but doubted whether minute disease of the ovary could be recognized by a simple incision of the organ, and thought the whole ovary ought to be removed. He was convinced that in many cases the ovaries and tubes have been removed when the trouble was entirely in the ureters.

Dr. Joseph Taber Johnson, of Washington, thought if the adhesions were broken up without taking out the ovary the disease would return, and cited a case confirming his belief. If there is much disease it is better to remove both ovaries than to subject the patient to the dangers of a second operation.

Dr. Polk agreed with Dr. Johnson and if there was cystic degeneration to any extent he would not leave the ovary in, but in many cases there are only one or two good-sized cysts and they can be removed without taking out the whole ovary and very few adhesions result, it not being necessary to close the incision in the ovary with sutures, unless to control hemorrhage from the cut ovarian surfaces. He believes adhesions are a matter of no great importance, except for a short time after the operation.

The Society then adjourned, to meet in Washington, the third Tuesday in September, 1891, to take part in the Congress of American Physicians and Surgeons.

Among the social features of the session were luncheons tendered by Dr. Mann, of Buffalo, Dr. Ford, of Utica, and Dr. Stansbury Sutton, of Pittsburg. The Society made an excursion to Niagara Falls, which was followed by a dinner, as guests of the Buffalo Medical Club.

Correspondence.

OUR PARIS LETTER.

(From our Special Correspondent.)

THE CAUSE AND TREATMENT OF SEA-SICKNESS—CEREBRAL SURGERY—DRAINING THE LATERAL VENTRICLE FOR HYDROCEPHALUS—THE TREATMENT OF DIARRHŒA BY LACTIC ACID—RELATIVE ADVANTAGES OF VARIOUS PREPARATIONS OF DIGITALIS—THE RELATIONS OF DIPHTHERIA AND FACIAL ERYSIPELAS—NAPHTHOL IN PURULENT OPHTHALMIA.

Paris, September 20, 1890.

Till now sea-sickness has been considered the opprobrium of medicine, as no remedy has as yet been discovered for the relief or cure of this most distressing affection. Various theories have been propounded to explain its nature or pathology, but not much light has been thrown on the subject. Some authors attribute the proximate cause to anæmia of the brain, others to the general commotion of the system, particularly of the stomach and bowels caused by the movements of the ship. One critic facetiously remarked that the only advance that has been made was to give the term sea-sickness a scientific name by calling it "naupathy." Professor Charles Richet, in a letter to the *Progrès Médica'*, states that he had employed the sulphate of quinine in a subject who was extremely susceptible to sea-sickness. The result was excellent; everybody on board was sick, but the subject in question felt absolutely nothing. M. Richet compared this fact with what is observed in Menière's disease, the symptoms of which recalled those of sea-sickness, and where the sulphate of quinine often succeeds. The mode of employment recommended by M. Richet is as follows: One gramme of sulphate of quinine in a wafer, to be given every two hours at least, and four hours at most, before embarking. None of the other precautions usually prescribed for such cases, as, for example, the horizontal position, which is always efficacious, should be neglected. Narcotics are of little or no use.

Cerebral surgery continues its audacious performances. According to the *Journal de la Santé*, Dr. Thinar, of Brussels, lately operated on a hydrocephalic child of three years of age. The patient having been put under chloroform, the skull was trephined at its right lateral pariety, when, the cerebral substance being exposed to view, an India-rubber sound was introduced to a depth of five or six centimetres, in order to reach the lateral ventricle. An increased quantity of liquid was produced, and the sound was left in the ventricle in order to permit the continuation of the escape of liquid. This is the first time that an operation of this sort had been attempted in Europe. Practised twice in America, it completely failed on both occasions, which does not prove much in favor of the operation, and is not very hopeful of future success.

At a recent meeting of the Société Médicale des Hôpitaux, Professor Hayem communicated a note on the treatment of diarrhœa by lactic acid. Among adults he has had no failures. He recommends the medicament to be prescribed in doses of from 10 to 15 grammes, in

the form of lemonade, as follows: Lactic acid, from 10 to 15 grammes; syrup of mulberry, 200 grammes; water, 500 grammes; to be drank by half a glass at a time between meals. Lactic acid acts very well in the diarrhœa of typhics and in sporadic diarrhœa. M. Hayem states that he would not hesitate to recommend it as a prophylactic and as a curative against epidemic cholera.

At the Société de Thérapeutique a discussion took place on the relative advantages of the various preparations of digitalis. As regards digitaline Dr. Huchard stated that he was in the habit of prescribing it in one massive dose, that is to say, at one time, for one day only, fifty drops of a solution of one-thousandth of crystallized digitaline. In this he followed the example of Professor Potain, who does not prescribe the medicine in any other form. Dr. Huchard has employed the same preparation for the last two years, and he finds that it has for advantage to be equally dosed and not producing any accident of gastric intolerance. Under the influence of this medication diuresis is promptly augmented; sometimes at the end of the first day, often from the second day, the medium quantity of urine is from three to four litres per day, and it has amounted to six and seven litres. These remarkable results are, therefore, in complète contradiction with those of other authors, who think that digitaline possesses a diuretic action far inferior to infusions of digitalis. Moreover, the crystallized digitaline employed by Dr. Huchard produced the same effects as the other preparations of digitalis on the circulatory system.

The *Journal de la Santé* relates that Dr. Babchinski, a Russian physician, having had his son affected with grave diphtheria, erysipelas of the face suddenly supervened, which was followed by a remarkable change in the state of the patient—the fever fell, the false membranes disappeared, and the patient was cured in a short time. Dr. Babchinski had observed in several other patients a similar improvement taking place after the disappearance of an attack of erysipelas, and in one of them the erysipelas had invaded the leg. These facts suggested to this physician the idea of inoculating a diphtheritic patient with blood taken from a patient affected with erysipelas. Erysipelas declared itself, things passed as in the preceding case, and the child which was inoculated was cured. Subsequently he practised inoculations on other diphtheritic patients with cultures of microbes of erysipelas, cultivated on agar-agar, and constantly the manifestations of diphtheria disappeared. It may be added that, besides the inoculations, the patients had not been submitted to any other special medication whatever, and that in no case did erysipelas present any grave symptom. Dr. Babchinski concludes his note with the following remarks: "If my observations and my experiments are confirmed, this treatment of diphtheria will be easy and certain, and this malady will no longer be dreaded."

Dr. Budin, accoucheur at the Charity Hospital, vaunts the use of naphthol in the treatment of purulent ophthalmia. He states that with naphthol the swelling of the eyelids yields rapidly, the cauterizations need not be practised so frequently, and if the naphthol cannot replace the nitrate of silver, it renders great service as an adjuvant in the treatment of purulent ophthalmia; it is far preferable to boric water. Dr. Budin cites, in his clinical lectures, an observation in which boric water not having produced any amelioration whatever, with naphthol the conjunctivitis, which had lasted a long time, disappeared rapidly. Since the researches of Dr. Budin, the naphthol A, which is twice more antiseptic than the naphthol B, has been adopted with great advantage. The non-alcoholized solution is that employed, and is composed as follows: Naphthol A, 20 centigrammes; distilled water, 1,000 grammes.

Two Drops of Creasote made from beech tar, given with a little water, is said to be a specific for hiccough arising from drunkenness.

HYDROTHERAPY IN EUROPE.

To the Editor of the Medical Record.

Sir: A desire to ascertain the true status of hydrotherapy in Europe, and to observe the practical working of the methods adopted by prominent specialists in this line, has led me to visit the most noted institutions on the Continent.

My gleanings in this important field, which has thus far lain comparatively fallow and uncultivated in our own country, may be of interest to your readers.

Being aware that the best clinical observers in Europe, of whom Nothnagel, Leyden, Semnola, Cantani, Ziemssen, Dujardin-Beaumetz are representatives in their respective countries, constantly advise the application of water as an important therapeutic agent, I was not surprised to discover, upon personal contact with physicians and patients who consult these authorities, and especially the eminent neurologists like Charcot and Erb, that hydrotherapy is almost exclusively relied upon in the treatment of chronic diseases. A patient of Professor Binswanger of Jena, for instance, assured me that with the exception of one powder, his case of neurasthenia was treated exclusively by water. But while there exists a marked unanimity on the subject of *chronic disease*, quite the reverse is the case with regard to *acute diseases*, in which hydrotherapy appears to have lost rather than gained in Germany during the past decennium. A conversation with Professor Fraenkel, during a visit to the magnificent new "Staedtische Krankenhaus zu Urban," in Berlin, furnished a clue to this paradox. "Although as a pupil of Traube," said he, "I learned to value hydrotherapy very highly, I now abstain from baths entirely in fever, because, in Germany, we have come to be opposed to all antipyretics in typhoid fever."

The inference from this assertion would be, that because antipyrine and its congeners have proven faithless to the trust so unscientifically imposed upon them, in not jugulating fevers, and because the cold bath has from the infancy of medicine occupied the position of the chief antipyretic, water must now share the fate of the chemical antipyretics of modern times, and with them be cast into everlasting oblivion. The fallacy of this reasoning is transparent to the reflecting mind.

Antipyrine and its congeners have not only failed as cures of fever, but even when used as symptomatics their effect is, as I have repeatedly argued, detrimental (not so much as heart depressants, but) by interfering with the elimination of excrementitious material from the kidneys, etc., and as Cantani has said (on antipyresis), before the recent International Congress, because they suppress the capacity of a reaction, of which the fever process is a manifestation, and which is a potent factor in the elimination of the disease-producing elements.

That the cold bath is not a good antipyretic I have on several occasions held before our city societies. There is nothing more positively demonstrable than the fact that as a reducer of temperature the cold bath of Brand is far inferior to the lukewarm continuous bath of Riess, and that both are excelled in antithermic effect by a full dose of antipyrine or antifebrine. The reduction of temperature by the cold bath is small, as a rule, in typhoid fever; it is therefore not an antithermic agent in this disease, but a refreshing agent, through reflex action from the periphery upon the nerve-centres, from which the whole machinery of the body receives its tone, its force, its very life.

Indeed Liebermeister has successfully labored to show that the cold bath secondarily actually increases heat production within the body.

We may find in Cantani's late address on antipyresis the answer of an able practical clinician to Professor Fraenkel's erroneous postulate. "We must say (page 17) that an unprejudiced clinical observation may gladly praise the one (hydriatic abstraction of heat) as useful, while it recognizes the other (reduction of heat by chemical antipyretics) as harmful."

From this brief outline it would appear that hydrotherapy in acute disease is now in a transition stage. From this it will emerge as a remedial measure that will endure for ages. This assertion is justified by the facts brought out in the recent discussion of the Société Médicale des Hôpitaux in this city, which supports the views, long striven against here, of the best clinical teachers of Germany—Ziemssen, Struempell, Nothnagel, Senator, Liebermeister, Juergenssen, and others, who said in 1885 (Cong. fuer Int. Med.) that until we can find an antiinfectious specific, the cold bath is our best remedy in typhoid fever. But aside from this clinical test we have, in the investigations of Maragliano with the pletysmograph, positive demonstration that the rise of temperature is coincident with a contraction of the peripheral vessels in the skin, which begins even before the rise, and reaches its maximum when the maximum temperature has been attained; and that the lowering of temperature in fever is preceded by a dilatation of the superficial vessels.

These investigations support Bettelheim's and Geigel's discovery that antipyretics always reduce temperature by causing dilatation of the skin-vessels, and thus determining heat-loss. This is a most positive confirmation of the well-known fever theory of Traube, that rise of temperature is a direct consequence of the diminished heat-loss resulting from contraction of the vessels. That Liebermeister erred in the dictum that all heat abstraction from the periphery determines an increased tissue metamorphosis and heat-production within, is proven by the exact experiments of Speck and Loewy in Zunz's laboratory, which demonstrate clearly that this is the case only when action of the muscles is not avoided. These exact investigations are, as Dr. Winternitz told me, with pardonable pride, a complete confirmation of the theory defended by him for twenty-five years, and of the rationality of the basis of his therapeutic teachings.

This is not the place to elaborate a question so pregnant with import to suffering humanity. In the forthcoming work of Professor Winternitz his position will be so clearly demonstrated by exact sphygmographic and other mathematical and chemical tests, made by his very able, earnest, and conscientious assistant, Dr. Pospischl (to whom I am indebted for many courtesies), that hydrotherapy will be placed in a permanent position as the most valuable agent in acute diseases. Dr. Winternitz is not an advocate of prolonged cold baths or of very low temperatures. For more than a quarter of a century he has shown again and again that temperature reduction is not the chief aim of hydriatic fever treatment, but that the reflex effect upon the nerve-centres, upon the heart, etc., also may be produced by cold packs, ablutions, and half baths in which the water is constantly agitated. The profession and the public will be more favorably disposed to this treatment than they have been to the full cold (Brand) bath, whose success has been so completely established by statistical evidence.

While on this subject it may be mentioned that I received a very cordial invitation from Dr. Brand to visit him in Stettin, with the courteous offer to aid me in the pursuit of my studies, and that I visited the Garrison Hospital of Munich, whose *chief*, Dr. A. Vogl, has given the world the most remarkable statistical record in medical history. His barracks for typhoid fever are crudely constructed of wooden pavilions, so completely occupied by large windows that they resemble greenhouses. At the upper end of these long barracks, containing forty beds, stand two zinc bath-tubs, just under two faucets. The patients are carried to the tubs, assistance being plentiful (four nurses to sixteen patients), and placed in a full bath of 65° F., active friction being constantly made to prevent chilling. I have fully described the method in papers read before our societies, and referred to the remarkable result of an average of twenty-seven per cent. mortality during the past ten years. These statistics have been doubted, but I am convinced by inquiry, from the assistant of Dr. Vogl, into the system adopted in these records that they are absolutely reliable. No one knowing Dr. Vogl personally, and recognizing his great personal worth and eminent position, would doubt this fact.

In hydrotherapy in chronic disease there may be said to exist two sects—the Germans resort to wet pack, foot, sitz, and other local baths and douches, while the French, following Fleury, apply douches almost exclusively. Indeed the methods are amusingly characteristic of the people. The German may be readily induced to lie an hour in a wet pack, and, as I have seen them every morning in large numbers at Kaltenleutgeben, sleep soundly in them until aroused for the half-bath. The Frenchman would chafe under such restraint. The German method, as elaborated scientifically by Professer Winternitz, offers every modification of hydrotherapy. But the brevity of the douche treatment is a great advantage. I was impressed during my visit to Duval, the directeur of the Institute Hydrotherapeutique de l'Arc de Triomphe (who, by the way, spoke lovingly of our lamented Marion Sims), by the rapidity of his work. The attendant opened the door, with "Prêt, monsieur," the doctor entered the douche-room; I heard a sound of splashing waters; a muffled, gasping exclamation, and in a moment the doctor again appeared in the office, from which he was again called in five minutes. This process was repeated many times during my visit. Much time is thus gained, a matter of importance to busy men and women, who may be suffering from neurasthenia and other ailments, not withdrawing them from business.

During the past month I have visited a large number of hydrotherapeutic establishments in Germany and France, most of which seemed to be directed by educated medical men, whose courtesy to me I gladly acknowledge.

In connection with this subject it may be of interest to refer to the fact, that since the days of Priessnitz watercure establishments under the management of laymen have sprung up. Until recently these were not numerous. Now there exists a society of Naturarzt, whose influence upon the public is pronounced and increasing. These men are usually teachers, clergymen, and even ordinary laborers. One institution in Gera which I visited is presided over by a weaver, whose success has enabled him to purchase the building. This man successfully treated one of my relatives for icterus following the *grippe*, the attending physician consenting. Impressed by this intelligent, yet uneducated Naturarzt, I was induced to visit the fountain-head of the "Nature-doctors," the "Von Zimmermann Institute" at Chemnitz. This is an imposing edifice occupying a lofty eminence, which overlooks a lovely valley in the rear and the smoking factory funnels and the distant mountains in front. Surrounded by tastefully laid out gardens a more beautiful sanitarium could not be imagined. It was endowed by a wealthy merchant, in grateful recognition of his recovery from a disease said to have been pronounced incurable by the regular faculty, but which yielded to the water treatment. Impressive as is the exterior of this institute, as well as the domiciliary arrangements, it proved with regard to hydrotherapy a delusion. The apparatus is of the crudest kind, baoly cared for; the attendants appeared to be active but illy informed. One of these told me that he required no thermometer, the hand being a sufficient guide, and that the temperature was of little consequence at any rate. They use raw silk instead of linen for their packs. Still these ignorant men, who are directed by a former army physician (who was absent), obtain such good results in chlorosis, functional nervous diseases, dyspepsia, rheumatism, and gout, that one is inclined to ask himself if such results may accrue from cleanliness, regulation of diet, improved habits, and abstention from medication, how much more might not be attained if the application of these means were guided by skilled and educated hands?

Among these "nature" doctors there are several types. One of these, Pfarrer Kneype, is now attracting almost as large and varied a *clientèle* as did Priessnitz in his day.

His success is the theme of conversation in all circles. His principle of water-cure is that the patient should be compelled to produce his own reaction. Instead of being rubbed dry, the patient is directed to walk until the damp shirt in which he is enveloped is dry. Walking barefoot in the dewy grass is a favorite method of this innovator, who has produced in addition a pharmacopœia of vegetable remedies that would make a Thompsonian eclectic green with envy. The novelty of the treatment, combined with the compulsory out-door exercise, and not a little of the faith cure element, have brought this plain priest, who labors not for gain, much fame.

As I was about to conclude this letter a copy of the Paris edition of the New York *Herald*, September 21st, was handed to me, containing an article, which evinces its paternity from a well-informed medical source, and which furnishes a corroboration of what I have long attempted to impress at home, in connection with the subject of this letter. Speaking of Brand's cold-bath method in acute diseases the writer says: "A certain number of attempts in this direction have been made in Germany, the country of therapeutical audacity and often temerity. The inference to be drawn is that although Brand's method had a hard time in gaining the confidence of physicians in France, it is now giving satisfactory proof of what it can do, and is destined to become the most efficient treatment for the majority of infectious diseases with high temperature and nervous symptoms." This means that it is on the point of entering into common practice, for physicians will appreciate it more and more when they try it regularly and resolutely, without being hampered by preconceived ideas.

SIMON BARUCH, M.D.

PARIS, September 20, 1890.

READY REMEDIES FOR ACCIDENTAL POISONING.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: As a large number of cases of poisoning by accident occur in the city and country, due to the selling of dangerous drugs to the laity, I venture to suggest that it would be well to have all druggists' labels so printed that under the name of the poisonous article its antidotes should appear in italics. For example:

POISON.

LAUDANUM.

ANTIDOTES.—*Strong infusion of coffee; arouse patient by shaking; ten-drop doses of tinct. belladonna; emetics.*

The simplest and nearest-at-hand antidotes should be given on the label, and these might be used by the family or friends while waiting for a doctor. "Scraping the ceiling with the fire-shovel," or the "white of egg," may save a valuable life in an emergency if thought of in time.

M. B. C.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from September 27 to October 4, 1890.

MORRIS, EDWARD R., Assistant Surgeon. Promoted September 17, 1890, to be Assistant Surgeon with rank of Captain, in accordance with the act of June 23, 1874.

CRAMPTON, LOUIS W., Captain and Assistant Surgeon, Fort Sheridan, Ill. Granted leave of absence for one month, to take effect about October 1, 1890. S. O. 80, par. 2, Division of the Missouri, St. Louis, Mo., September 30, 1890.

PHILLIPS, JOHN L., Captain and Assistant Surgeon. By direction of the Secretary of War, the leave of absence granted in S. O. 164, July 16, 1890, from this office, is extended two months. S. O. 228, par. 3. A. G. O., Washington, D. C., September 29, 1890.

OWENS, W. O., JR., Captain and Assistant Surgeon. In view of the abandonment of Fort Gibson, I. T., to which post he is at present assigned for station, is relieved from duty at that post, and will, upon the expiration of his present leave of absence, proceed to Fort Sill, Oklahoma Ter., and report to the commanding officer for duty. S. O. 125, Department of the Missouri, St. Louis, Mo., September 27, 1890.

PHILLIPS, J. L., Captain and Assistant Surgeon. In view of the abandonment of Fort Crawford, Col., to which post he is at present assigned for station, is relieved from duty at that post, and will, upon the expiration of his present leave of absence, proceed to Fort Logan, Col., and report to the commanding officer for duty. S. O. 135, par. 2, Department of the Missouri, St. Louis, Mo., September 27, 1890.

TESSON, LOUIS S., Captain and Assistant Surgeon, Fort Sidney, Neb. Granted leave of absence for twenty days, to take effect when his services can be spared by his post commander. S. O. 72, Department of the Platte, Omaha, Neb., September 25, 1890.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 4, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	60	8
Scarlet fever	27	1
Cerebro-spinal meningitis	1	4
Measles	45	3

Small-pox	0	0
Cholera	0	0
Pertussis	0	0

The Hotel Dieu Four Hundred Years Ago.—In a work by M. Luce, recently published, on "France during the Hundred Years' War," we get a curious picture of the well-known hospital, the Hotel Dieu, of Paris. The history shows the fourteenth century in its struggle against the misery of the poor, and also the private contention, not unfamiliar to our own times, between the surgeons and the nurses of a great hospital. The terrible mortality of the Middle Ages (in which the average duration of life was seventeen years) may be gauged from the fact that in a single year (1368–69) the Hotel Dieu buried over twenty-two thousand of its patients. The number of the sick was, it must be admitted, correspondingly great. The accounts of the prioress of the Hotel Dieu show that no fewer than thirty-five thousand sheets were daily supplied in the wards. Another Paris hospital, during the same year, in addition to its ordinary patients, gave shelter to nearly seventeen thousand pilgrims on their way to St. Michael's Mount, and other shrines. According to the author, if the medical services were slight, there was no lack of shelter; a good bed with clean sheets and six warm blankets, the kind suited to refined women, and such tisane or theriac as the services of the time could furnish, were apparently within the reach of all who needed them.

Tobacco Smoke passed through cotton-wool charged with pyrogallic acid is said to be freed from nicotine.

THE SENSATION OF ITCHING.[1]

BY EDWARD BENNET BRONSON, M.D.,

PROFESSOR OF DERMATOLOGY IN THE NEW YORK POLYCLINIC.

IT is a somewhat remarkable fact that a manifestation of cutaneous irritability so common as itching, and one with which as a symptom we are so familiar, has been almost entirely neglected as an independent subject of study. Of other anomalies of sensation, such as hyperæsthesia, anæsthesia, and pain, we have tolerably clear and definite notions. But who has explained for us the cause and nature of pruritus? What is this disturbance of sensation? To say that it is a form of cutaneous irritation that produces an inclination to scratch (for such is the usual definition), is as much as to tell us that itching is the desire to scratch. We itch to scratch and scratch because we itch. It is clearly a nervous disturbance of some sort; but what produces it and why scratching relieves it are questions which, so far as I know, have never been satisfactorily answered.

Itching, or something closely akin to it, is in all probability common to most if not all animals, though most marked in those that are hairy or feathered. Though often provoked by irritants extraneous to the body, it also is very frequently spontaneous, occurring under apparently healthy conditions, as well as in disease. When in repose an animal will often by various actions or movements, that answer more or less to the act of scratching, betray the fact that it itches, even when the skin is neither diseased nor molested by insects. And in the human subject spontaneous itching is common enough, and it is often only the sense of propriety that represses the inclination to the desired gratification. The child stripped for bed and begging to have his back scratched is more in the state of nature. Let anyone sit quietly for a moment fixing attention upon the skin and the chances are that sooner or later he will become conscious of a slight intrusive irritation at some point, a prickling or picking sensation, and the longer it lasts the more it demands attention. You pass the finger or nail over the irritated point and it is gone. What was it? Was it pain? If all uneasiness is pain, yes. If desire is pain, yes. If the inclination to stretch the limbs, to wink the eyes, to eat is pain, so is this trifling disturbance of sensation, this desire to scratch.

In severe itching, and especially in disease, the feeling becomes more complex. This is evident from the multiplicity of expressions used to describe it—such as "tickling," "prickling," "picking," "creeping," "crawling." But always there goes with it the impression of intrusive contact, together with the longing to scratch. Closely connected with it are other sensations that are secondary and probably entirely independent of the feeling of itching. Such are the smarting, burning, or stinging sensations which only accidentally are coincident with this feeling and are clearly painful sensations. They are not only independent of the pruritus but are distinctly antipathic to it. As soon as the scratching becomes violent enough to produce a painful sensation the itching is, temporarily at least, extinguished. Furthermore, any painful sensation of the skin would most likely be aggravated by scratching. Though pruritus has sometimes been described as a variety or phase of pain their characters are totally dissimilar. The feeling of pruritus always carries with it the suggestion of something extraneous to the body. There is in the sensation an element of objectivity, while in a painful sensation the feeling is purely subjective. In the one there is the consciousness, whether deceived or not, of something outside of self. In the other, one is only conscious of the suffering. One is resentment, with the instinct to repel an attack, an intrusion; the other is a suffering self-consciousness without cognizance of the producing agent. One is a longing desire to resist, the other the passive endurance of penalty.

Though a certain consciousness of the agent may accompany pain it is very different from that in pruritus. One resents a stinging blow, as the lash of a whip. The soldier struck by a spent ball curses the enemy. But there is no consciousness of the presence of a whip in the smarting flesh, nor of an enemy in the aching limb. Cause and effect may be a mile apart; it is only the effect that remains, and of that only is the subject directly conscious. At the first instant of injury the organ of touch is sufficiently involved to give intimation of the locality injured and perhaps something of the quality of the injurious agent, but the sensation of pain *per se* gives no such intimation. It is simply a passive condition. In pruritus, on the other hand, cause and effect are presented to consciousness as one. The consciousness of the object, the irritant, is not an instantaneous intimation, but persists while the itching lasts.

But if puritus is not pain in the ordinary acceptation of the word, is it any more nearly related to the special sense of touch? What are its relations to the so-called special senses on the one hand and to common sensation on the other?

The distinction recognized between common and special sensation is that while the former communicates only impressions of subjective states of the body, the latter imparts knowledge of external things. Through the former we are made aware only of somatic conditions, changes or phenomena that transpire in the *ego*; while through the latter we take cognizance of changes or phenomena in the outside world, the *non ego*. By means of the special senses the presentations to consciousness are such that we are enabled to appreciate the qualities of external objects, and through a series of such presentations to know, to perceive, what the thing producing the sensations is. Such definite and competent sensations, perceptive sensations, exist only in connection with the senses of seeing, hearing, smelling, tasting, and touching. All other sensations, though widely diverse in character among themselves, are little more than varying phases of ease and discomfort, of well being and ill-being, of desire and gratification. Except through association of ideas, through imagination, they have no connection in consciousness with the outside world.

But notwithstanding the fact that the special senses in their present state are so far removed, in respect to the knowledge they yield to consciousness, from common sensation, there doubtless was a period when the distinction did not exist. Their differentiation has been the result of gradual and long-continued processes of evolution. There can be little question that the sensory organs to which the several senses owe their special attributes have all originally developed from simple nerve endings that

[1] Read before the American Dermatological Association, September 2, 1890.

could give but the vaguest intimations of external objects. At the very beginning there was simply a common sensitive exterior that reacted to the various irritations it encountered in general, and more or less indefinite movements of the protoplasmic mass. Beginning with the protozoa, the protrusion of pseudopodia, as in the rhizopoda, was among the first simple attempts at adaptation. In further progress and by a similar process tentacles and sensitive hairs appeared. Nerve-terminals, at first homogeneous, gradually resolved themselves for division of labor into special organs. From the common sensitive exterior there were separated in the course of time the optic and auditory vesicles with nerve-filaments distributed over their interiors. Over little clefts or depressions in the integument other nerve-filaments became differentiated as the organs of smell and taste; while the common integument, retaining its primitive common sensations, evolved a special sense of touch. The facts of evolution are exactly reflected in the parallel development of the embryo. Out of the ectoderm or outermost germ-layer the organs of special sense are gradually developed and traverse the same general phases of progress, as may be traced in the evolution of the higher creations of the animal kingdom. Both ontogenetically and phylogenetically the simple origin of the organs of sense appears too obvious for dispute. Diverse in their individual characters as well as in their divergent routes of descent, as these organs are, they all converge toward a common source in a general sensitive exterior composed of homogeneous nerves.

The earliest attempts at specialization in this common sensitive exterior could have effected little more than certain modifications of common sensation. To fix the exact period when these primitive modifications began to develop into the special senses, through which the animal is placed in intelligent communication with its environment, is needless, if it were possible. It must in general correspond to that period when the animal's movements first showed indications of purpose. When the amœba comes in contact with a foreign substance the reflex movements that are excited are vague, haphazard, and apparently purposeless. According as the contact occurs, or as the object is presented to it, the animal shrinks away from it, or contracting about it envelops it in its interior, where, should the substance happen to be nutritious, it may be absorbed. The first beginnings of adaptation would naturally be associated with the simple consciousness of contact, a sort of primitive sense of touch. With the first intimation to the animal of a difference between one kind of contact and another we reach the threshold of an objective consciousness and the commencement of perceptive sensation. Partly empirically and partly through natural selection the differentiation of sensations gradually proceeds. The animal now directs its movements with intelligence and purpose. It acquires the ability not only to feel but to perceive. It can select and seek its food, evade or attack its foes, and so gradually is equipped for the struggle for life. Thus as all the sensory organs can be traced to one elementary and homogeneous organ, so all sensations, whether common, special, or perceptive, may be traced to one undifferentiated and elementary sensation, which is common sensation.

In this evolution the impelling force, the directing impulse, has been derived from the two grand principles of life known as the instinct of self-preservation and the instinct of reproduction. To one or the other of these instincts every sensation that arises in the body must be directly or indirectly referred. All sensations, as we have seen, were originally tegumentary. To the common integument must be ascribed the source and potentiality of all sensations. As the result of specialization most of these sensations have been withdrawn from the exterior. What traces of the special senses thus abstracted still persist in the skin may be infinitesimal. That such traces do exist there can be little doubt. At least that the skin is sensible to waves of light has been demonstrated by curious experiments. There still remains to the skin and adjacent mucous orifices a variety of sensations, some of them undifferentiated from the elementary common sensation, others more specialized, including a special sense with perceptive faculties, and finally the most important representative of the reproductive instinct, the aphrodisiac sense.

The objective or perceptive sensations of the skin constitute what is known as the sense of touch or tactile sense. It is the sense by which we apprehend the form, size, location, temperature, and various other qualities of external objects, such as softness, hardness, smoothness, roughness and the like. Many of its attributes it owes to the so-called muscular sense, which in many tactile operations cannot be disassociated from the sense of touch. Moreover, the sense of temperature is really an independent sense, depending actually upon nerve-terminations especially adapted to this purpose. This independence has long been recognized in certain pathological conditions, where one sense has been annulled irrespective of the other, while the recent experiments of Goldscheider have established the fact still more positively. Goldscheider, having first established experimentally that there were certain areas of the skin sensitive to touch and others to temperature, on exercising these areas found microscopically that the innervation was also distinct.

Of the existence of a specialized sense of touch there is no question, nor that it is limited to the skin and adjacent mucous orifices. It is not wholly expressed by pressure sense, for it is incomplete without the accessory muscular and temperature senses. Again, there is a sense of contact, the sense of being touched without perceptible pressure, which has come down from the earliest periods of animal development and which, originally at least, must have been unassociated with tactile sense as we now understand it. Before any consciousness of pressure exists, we are sensible of contact. But something more than this is necessary before there can be anything like sense of form or quality. It is this sense of contact, doubtless, that is the beginning—the threshold of pressure sense.

What is meant, then, by the phrase "sense of touch"? As we have seen, it has a composite character, but though made up of heterogeneous elements the perceptions that flow from it are as definite and as distinctly individualized as those afforded by its sister senses. Nevertheless the term is a vague one and inadequately expresses the sense implied. As we have seen, simply touching an object, simple contact, evokes a sensation or sensations that are only preliminary to the specialized sense. We become conscious of local contact before any quality of the object touched can be distinguished. It is only when the feeling of resistance begins and we are aware of pressure that there can be any appreciation of quality. It may be said that such appreciation is purely an intellectual act; but as the brain would be incapable of appreciating the different tones in sound except for the organ of Corti, or the different colors of the spectrum except for the intervention of the retina, so is it probable that the tactile perceptions would not exist but for the presence of special sense organs in the skin. Such organs have been aptly termed "organs of reinforcement."

The expression, therefore, for the special perceptive sense that belongs to the skin should imply more than mere touch. It is not simply sense of contact, it is not simply feeling, but it is contact plus something else; it is feeling *of* the object as well as simple feeling it. The word palpation better expresses the act whereby the sense is evoked, but etymologically that term would be too restricted. Palpation (from *palpus*, the palm) relates more particularly to manipulation; it is feeling with the hand only. A still better term would be pselaphesia. The Greek ψηλάφησις conveys the idea of feeling for or of a thing, or groping as a blind man or as one in the dark. The Latin *tactus* (from *tango*), on the other hand, signifies only the act of touching as expressed in the words tangent

and contact. The only sense with which the skin is endowed that can properly be called perceptive, and that is worthy of comparison with seeing, hearing, smelling, and tasting, is the sense of pselaphesia. It includes the sense of contact, which, as we have seen, is its most primitive form; its more important element is pressure sense, while the temperature and muscular senses are more or less essential auxiliaries. Common sensation is represented in the integument in its highest positive aspect by the voluptuous sensations, in its lowest negative aspect by pain.

From analogy with its sister senses, the sense of pselaphesia should depend upon a special arrangement and adaptation of the nerve-endings. There should be an organ or "organs of reinforcement." It is scarcely probable that in the skin there is any such highly specialized arrangement as in the eye and ear, and yet we find nervous structures in the skin whose distribution and peculiar development mark them as organs of special importance to cutaneous sensation. What the exact functions of these different structures are is yet uncertain. It is little more than conjecture what special parts are played by the corpuscles of Meissner or those of Pacini, by the terminal bulbs of Krause, the nerve plexuses beneath the epidermis and about the hair-follicles, the tactile cells of Merkel, the free nerve-endings, and, finally, the nerve-distributions to the epidermis, including the remarkable intracellular nerves described by Pfitzner and Unna. Suffice it for the present to say, that from analogy we should expect the most highly developed of these to correspond to the most highly developed sense, to pselaphesia.

To turn from this long, though not purposeless digression, what relation to all these sensory organs of the skin and to their various sensations does the sensation of itching bear?

First of all, the sensations of pruritus must have to do with nerves that are very superficial. There is no reason to believe that of pressure-sense, properly so-called, there is the slightest intimation. If, with the end of my pencil I gently approach a sensitive surface, such, for example, as the cheek or one of the *alæ nasi*, I become aware of a sense of contact the instant the surface is touched. A little pressure and I receive the impression of a smooth, rounded body, and a moment later a slight sensation of coolness. I have a perceptive sensation. If, instead of making any pressure, the pencil be retained just at the point of contact, presently a feeling of annoying irritation is excited. Still more marked is this irritation if, instead of using the pencil the part be lightly touched with a pointed wisp of soft paper or feather. There is elicited directly the sensation of a minute local shock, associated with an instinctive desire to escape from the irritating cause. If the same be repeated the excitement of the part becomes so great that the desire to rub or scratch it becomes almost irresistible. This sensation is pruritus, and it is evidently a nervous disturbance provoked by touching the sensitive surface What and where is this disturbance, and why should it be apparently so much greater than would be produced by a much more forcible contact?

First, how is it related to pselaphesia? The certain amount of pressure necessary to evoke this special sense implies that the organs on which it depends lie deep in the skin, and are doubtless those highly developed nerve-structures that are situated below the epidermis. It is evident that whatever connection the mere sense of contact may have with these organs it does not bring them actively into play. It is a well-known fact that in certain pathological states apselaphesia may coexist with hyperæsthesia of the surface, *i.e.*, an exaggerated sensitiveness to impressions of contact. Moreover, those areas of the body most highly endowed with special tactile sense, with the sense of pselaphesia, are by no means necessarily the ones most sensitive to contact; nor are they to pruritus. While itching has no apparent connection with the sense of pselaphesia, it cannot be disassociated from the primary sense of touch, the sense of contact. Now, obviously, this sense of contact should pertain to those nerve-endings but slightly differentiated and those most superficial. Such nerves exist in abundance in the epidermis.

While I can present no absolute proof of the proposition, I believe there is sufficient evidence to locate the essential seat of pruritus in the epidermis. Itching is evoked by such irritants as act upon this tissue much more uniformly than by those that act on the derma. We have seen how it may be excited by external irritants that barely touch the surface without the least intimation of a pressure-sense. The itching that is commonly observed in connection with the healing of superficial wounds is not attributable to the granulating process. There is no itching in the granulations of an ulcer. It is only when the part begins to heal and to "skin over" that the itching begins. It is a symptom of keratoplasia, not of dermatoplasia. In those cutaneous diseases also that more especially affect the derma, itching is present only exceptionally. In the erythematous, erysipelatous, and phlegmonous inflammations the sensations are of a smarting, burning, or aching character, *i.e.*, painful sensation, and if ever pruritus it is because of secondary implication of the epidermis. Likewise, of papular affections, as, for example, in syphilodermata, that are characterized by infiltrations confined to the corium or papillary body. If itching occur it is due to a similar and accidental implication. On the other hand, the essentially pruriginous affections, such as eczema, pemphigus, scabies, or lichen planus, are those invariably associated with decided trophic changes in the epidermis. In urticaria the implication of the epidermis is not so obvious, but as shown by Unna, urticaria is not primarily or essentially an inflammatory disease. It is often a neurosis and the itching is the primary factor, an irritation reflected to the terminal nerves from the nervous centres. The œdematous effusion that accompanies it, together with the local ischæmia, is doubtless the direct effect of muscular spasm.

However provoked, the sensation of itching is always associated with a presentiment to consciousness as though a foreign body were in contact with the surface. It is that sensation that experience through many stages of animal life has taught is often followed by a prick or a sting, and the inclination to escape the threatened hurt has grown into an animal instinct. The sense of contact at a minute portion of the sensitive surface is immediately interpreted to mean a miniature attack that must be repelled. If no attack has really been made, but only the threat, the intimation, then the excitement should disappear without returning the moment the cause producing the sense of contact is withdrawn. But it is the peculiarity of itching that it persists in spite of such withdrawal, and is only relieved by the act of scratching. It seems as though the contact, or whatever the change may be that gives rise to the irritation, produces a molecular commotion in the nerves that goes on like the jangling of an electric bell, with a continuance of the sensation until such time as the surcharge of nervous energy is released. In pselaphesia the nerve-force, or the molecular vibrations excited by the impact, is directly transmuted into some intelligent form of activity and the accumulation of nerve excitation—the nervous engorgement—does not occur. The circuit is complete with no point of resistance intervening to create obstruction, and so commotion.

With regard to the sensations of pain, the view was maintained by Funke[1] that they passed into the gray tracts of the spinal cord, where their further progress was arrested; while tactile sensations (the sensations of pselaphesia) traverse the less resisting white tracts and thence passed directly to the brain. Whether this explanation would apply also to the sensation of itching, whether the obstruc-

[1] See in Hermann's Physiologie (1879, iii., 2). Physiologie der Hautempfindungen und der Gemeingefühle.

tion that produces it is the same as for painful sensations, is a question that can neither be affirmed nor denied. It may be that the same process which produces what is called pain when proceeding from nerves deeply seated becomes itching if it starts from the nerves of the epidermis. Or, on the other hand, it might be alleged that the only difference lies in the amount or severity of the irritation, the nerves involved being the same. There are reasons, however, for believing that the epidermic nerves are not susceptible to pain. If with a knife we gradually pare away the epidermis, or if we thrust a fine needle through it, no pain is produced until it reaches the papillary body—until it "goes to the quick," as the common phrase is. But it may be objected that neither does this cause itching. The explanation is easy: An essential condition to the production of pruritus is the uncertainty, the vague and indefinite character of the sensation. The impression that the knife or needle produces as it forces its way through or between the cells of the epidermis is one which offers a clear and interpretable presentment to the sensorium, the sensation undergoes immediate transmutation into other forms of nerve-activity, thus obviating the accumulation or stasis of nerve-force. It is a definite and perceptive sensation, which doubtless calls into play the special organs of pselaphesia that may serve to turn the course of the molecular vibrations into the direct channels of the spinal cord. *A priori* reasons for differentiating pain from pruritus have been given already. We have seen that they are not only inconsistent with, but antipathic to each other. The means to which the animal instinctively resorts for their relief are distinctly opposed to each other. While pain demands rest, pruritus incites to action. It is also probable that they engage distinct elements of the nervous system.

The reflex muscular movements excited by itching doubtless had for their object originally the expulsion of a foreign body, often an insect. Such movements are frequently spontaneous and more or less unconscious. Analogous responsive muscular movements are seen in sternutation and the act of coughing. The tickling sensations of the nasal or laryngeal mucous membranes which are their provocation correspond very closely to cutaneous itching. But the relief afforded by sneezing is not wholly explained by the expulsion of the irritating substance, but, partly, by the fact that the effort affords an avenue of escape for the retained nerve-force, a means for the transmutation of this force into muscular energy. In those animals in which the platysma myoides is more highly developed than in man, as in the horse and bovine genera, a certain relief may be afforded to pruritic sensation through its energetic contractions, which is not wholly due to expulsion of the insect or whatever else may have caused the sensation. The same tendency to dissipate pruritic irritation through liberation of muscular force is evinced in the cutis anserina as well as in the hypertrophy of the arrectores pili muscles observed in many pruriginous diseases. May it not be that the changes in urticaria are the consequence of misdirected and ineffectual efforts of the cutaneous muscles to expel an irritant that produces on the sensorium the counterfeit presentment of some tangible body, as it were an offensive insect?

With regard to the effect of scratching in relieving itching, it is analogous to that produced by muscular exertion. Both cause a deflection of the pruritic irritation into other and freer channels. In the action of scratching there is substituted a decided and definite sensation for one that is simply vague and incomplete. It is the substitution of an effective energy for an ineffectual vexation.

Thus we arrive at something like a rational explanation of what itching is, why the sensation is attended with greater perturbation than are sensations produced by more tangible and appreciable contacts, and, finally, why it is relieved by scratching. Inasmuch as the presentations it yields to consciousness are vague and indefinite, it is closely related to common sensation, but inasmuch as it contains the glimmerings of an objective sense it is just one stage removed from it. It concerns those primitive nerves of contact out of which originally were developed the organs of special sense. It disturbs sensibility that was the precursor of, and doubtless is preliminary to, the sense of pselaphesia. Inasmuch as it concerns a sense of touch, it might be characterized as a paræsthesia of tactile sense; but regarding it more particularly as a disturbance due to interference with, to obstruction of, sensation, a condition in which there is vexation and annoyance of consciousness through the very indefiniteness and uncertainty of the sensations, the word paræsthesia does not express enough. Unfortunately, a term that most fitly expresses this condition has been already appropriated. Charcot has given the name "dysæsthesia" to a form of hyperæsthesia or paræsthesia occurring in myelitis, in which slight irritations of the surface, such as pinching, or the application of cold, are directly followed by painful vibratory sensations coursing up and down the region irritated, and often appearing symmetrically on the other side of the body, and that continue for a considerable time after the irritant has been withdrawn. In some respects, the dysæsthesia of Charcot corresponds to the phenomena of itching. At all events, the term employed is, etymologically at least, as appropriate to pruritus as to the painful sensations just described.

To explain in detail, or even enumerate all the different phases of itching would be impossible. While some of them are associated with pathological changes in the epidermis incident to certain cutaneous inflammations, others have their source more deeply situated and are referable to the nerve-centres. To the latter belong the form of neurosis of which pruritus is at the same time the symptom and sole appellation. Still other sources are doubtless to be found associated with apparently normal physiological conditions. It would seem as if a certain amount of scratching were, under some circumstances, salutary and requisite for an animal's integument, and that the sensation of itching were the necessary incitement. It would facilitate the fall of deciduous hairs, it would promote the normal exfoliation of the cuticle, which, under certain conditions, may not separate rapidly enough to permit the upward growth and expansion of the prickle-cells of the rete. It would tend to dislodge accumulations in the crypts of the skin, the sweat, and sebaceous follicles. While these represent the most obvious sources of itching, or provocations for scratching, there is another factor of which hitherto but little account has been taken.

Both the English words itch and itching and the Latin prurio and pruritus, in their secondary significations convey the idea of a longing, teasing desire. It is apparent in such expressions as, "the itch for gain," "the itch for praise," "the itch for scribbling;" while pruritus was commonly used by the Latins as a synonym for lascivious ness. There is an element of desire in the sensations of itching, and it is not improbable that the common, more or less definite recognition of this element is accountable for the derived or secondary meanings just alluded to. By desire in this connection something more is meant than merely the inclination to brush or scratch away a foreign body of which the sensation is apparently an intimation. It is, rather, a kind of desire closely akin to a lustful feeling, and one that sometimes makes scratching veritably a sensual indulgence. When pruritus reaches a certain degree of intensity, the subject is not content with that moderate amount of scratching that would ordinarily create a sufficient diversion to give relief, but there is a disposition to attack the itching surface with a vehemence that amounts to passion. Observe the motions of a dog when scratching. Sometimes its violent movements and muscular exertions betray an agitation that is not unlike the excitement of the sexual orgasm. The very act of scratching appears to evoke a condition of erethism and excitement that is far in excess of the mere pruritic irri-

tation. And in the human subject voluptuous feelings are not infrequently accessories to the sensation of itching. The delight of having one's back scratched is doubtless chiefly due to a longing for a voluptuous gratification that would not exist but for the pruritic titillation. When the scabious Scotchman at "the scratching-post" fervently ejaculates his "God bless the Duke of Argyle!" it is not only the negative satisfaction of relief that he feels, nor that combined with clannish loyalty, but his sensations include an element of positive enjoyment, he is having the pleasures of a gratified sense.

Recognizing this peculiar element of desire in pruritus, the sexual excitement and depraving tendencies that are so commonly associated with pruritus genitalium are most easily explained. But it is not so surprising that voluptuous sensations should attend itching here where they have their natural seat. Such sensations, however, are not confined to the genitals. They also affect the anus, where, more especially under certain conditions of moral perversion, as well as in association with pruritus ani, the erectile tissue in this situation may become the seat of erethism and in a measure there is excited an aphrodisiac sense. The female nipple also is susceptible of voluptuous sensations. These facts are well known, but the more general distribution of such sensations has received little consideration. They may be concomitants of itching in almost any situation. Persons subject to pruritus of the external auditory meatus are often in the habit of introducing the tip of the finger into the ear and making rapid vibratory movements that do not merely quell the itching but produce sensations that are distinctly voluptuous. The same is true, if in a less degree, of excessive rubbing or scratching of any surface that itches. There must be, however, the provocation of the pruritic irritation. By means of a violent excitation, superinduced by severe scratching, a liberation or discharge of nervous energy takes place accompanied by pleasurable sensations together with the relief of the pruritic irritation. A temporary inertia and rest follows and continues till a renewal of the pruritus provokes another resort to the same method of relief. How is this voluptuous feeling explained?

We have already seen that the only special senses that remained to the common integument after the differentiation of the special senses had taken place were the tactile senses, including the senses of contact, of pressure, and of temperature and the aphrodisiac sense. We saw also that the special sense of pselaphesia, while most highly developed in certain parts, existed to a greater or less degree over the whole surface. The same thing would seem to be true in a measure of aphrodisiac sense. Like the former, the latter is but a higher development of the primitive sense of contact. It has a special organ or instrument—the penis in the male, the clitoris in the female—much as pselaphesia has as its especial organ or instrument the hand; moreover, like the latter sense, though perhaps in a less degree, it is distributed over the entire cutaneous surface. Now sexual excitement has for its incentive the desire to gratify a special appetite, the agent or vehicle of which exists in the cutaneous nerves of contact. A plethora of nervous irritation is generated in the communicating nerve-centres which can only be released by a violent general agitation, an explosion, as it were, of nerve force, which is followed by equilibrium or by a minus state of depression. This is the sexual orgasm. The whole process is in close analogy with what we observe in connection with the relief of the intenser forms of itching by violent scratching. In each case the stored up energy has to do with the nerves of contact or the centres with which they directly communicate. These are the non-conductors that accumulate and retain the charge; the motory apparatus furnishes the channels through which the charge is conducted away in muscular energy.

As to why this process is attended with pleasurable sensations it suffices to say it satisfies a law of being. Gratification of appetite is a condition of life, either of the preservation of life or of the reproduction of life. The sexual, the aphrodisiac appetite can only be secondary to the instinct and appetites of self-preservation. It is the outcome of superabundant vitality. With this surplusage there is engendered the instinct, the impulse to increase, to give life, to make more life. The acme of this impulse is passion. When the increments of vital energy reach high-water mark there is tumultuous overflow, as in the syphon of an invisible spring.

It is not only in the aphrodisiac sense that this impulse is displayed. It actuates many of the highest intellectual and emotional faculties of man. Through it the mind conceives and reproduces; the purest sentiments of love are its offspring. In the control of all the forces, both of the body and of the mind, the reproductive instinct shares with the instinct of self preservation, the one being the opposite and the complement of the other, as in the conduct of life the spirit of altruism is the opposite and complement of the spirit of egoism. The one prompts to give more than it gets; the other to get more than it gives. The one dissipates energy; the other conserves force. One or the other of these two great instincts provides the mainspring of every human action and is the source of every animal appetite. Their combined product is life. Aphrodisiac sense, the lustful sense of contact, is but a phase, a single factor in the great domain of the instinct of reproduction. The appetite it engenders, the lust of the flesh, at the same time the most ignoble and the most dominating appetite of exuberant animal life, is but a means to the grand end, and when prodigal nature established its chief seat and "sacred" organ, she neglected to withdraw from the outlying regions of the general surface those traces of a congenetic sense that remain in a more or less primitive form, but nevertheless engage corresponding elements of the nervous system.

From the foregoing considerations I believe we are warranted in drawing the following conclusions:

I. That there is a sense of contact independent of the sense of pselaphesia.

II. That this sense of contact is the sense disturbed in pruritus.

III. That it concerns primarily, simple cutaneous nerves or nerve-endings, situated superficially and probably in the epidermis.

IV. That the disturbance in pruritus is of the nature of a dysæsthesia due to accumulated or obstructed nerve excitation with imperfect conduction of the generated force into correlated forms of nervous energy.

V. That scratching relieves itching by directing the excitation into freer channels of sensation, sometimes, especially when severe, substituting for the pruritus either painful or voluptuous sensations.

VI. That the voluptuous sensations that may attend pruritus are a manifestation of a generalized aphrodisiac sense, representing a phase of common sensation that has its source in the sense of contact.

Fatal Results of Lacing among Savages.—We have been told that the vices introduced by white men are depopulating the South Sea Islands, but now it would appear that white women are also responsible for the rapid depopulation of New Zealand. When female missionaries went among the Maoris they insisted that the Maori women should wear clothing. The latter could not be induced to overcome their prejudice against skirts, but discovering that the missionary women wore corsets, they decided that the latter was a garment not wholly devoid of merit. The result is that every Maori woman now goes about her daily work neatly clad in a corset laced as tightly as the united efforts of half a dozen stalwart warriors can lace it. Being unaccustomed to tight-lacing the women are dying off with great rapidity, and the repentant female missionaries now regret that they ever asked their dusky sisters to consider the question of clothing.

REPORT OF A CASE OF EXTIRPATION OF A CALCULUS FROM THE URETER BY THE COMBINED ABDOMINAL-LUMBAR SECTION.[1]

By RUFUS B. HALL, M.D.,

SURGEON TO THE CINCINNATI FREE HOSPITAL FOR WOMEN; PROFESSOR OF GYNECOLOGY AT THE CINCINNATI POLYCLINIC; CLINICAL LECTURER ON GYNECOLOGY AT MIAMI MEDICAL COLLEGE; FELLOW OF THE AMERICAN ASSOCIATION OF OBSTETRICIANS AND GYNECOLOGISTS, AND BRITISH GYNECOLOGICAL SOCIETY, ETC.

SEPTEMBER 2, 1889, I was consulted by Mrs. C——, of Columbus, O., who was referred to me by her family physician, Dr. J. F. Baldwin, of that city. The patient was thirty-six years old, mother of five children, the youngest four and one half years of age. She was a slender woman, never weighing more than one hundred and twenty pounds, and at the time of her visit her weight was about one hundred pounds. As a consequence of suffering she became anæmic and very nervous. She had always enjoyed good health previous to the present illness, which dated back to May, 1885, at which time she had an attack of pain that continued twelve hours, which was believed to be renal colic by her physician; when this subsided she felt as well as before, except a tenderness for a day or two over the region of the left kidney, and lower part of the abdomen. The physician was so certain that the cause of the pain was the passage of a stone from the left kidney that he had careful inspection made of the urine for days, expecting to find the calculus. In that he was dissappointed. Ever after the first attack she was subject to sudden and severe paroxysms of pain, varying in frequency from three to six weeks, for a period of about three years. The pain was located in the region of the left kidney at the commencement of each attack, but in an hour or so would diffuse itself over the whole abdomen. These paroxysms were usually of short duration, varying from three to six hours. During the last eighteen months, however, the attacks of pain remained longer, usually ten to twelve hours, and the intervals became shorter, about ten to fourteen days. Each paroxysm for a year or more was preceded by an uneasy sensation in the left side of abdomen for two or three hours before the severe pain came on. After trying morphia without giving the desired relief, her physician used inhalation of chloroform, keeping the patient under its influence until the paroxysm passed off. The husband, who is a very intelligent gentleman, under the direction and advice of his physician, soon learned to administer the chloroform to his wife during these attacks, keeping her under its influence until they passed off. He told me that he administered it frequently during the last eighteen months, giving her enough to make her wholly insensible. He would then remove the chloroform from her face and reapply it again when she showed signs of pain, using it much the same as it is used in labor until the attack passed off. In all of the paroxysms the pain would suddenly disappear just as it does in renal colic when the stone is forced from the ureter into the bladder. The fact that the stone could never be detected only served to make the diagnosis more obscure. The paroxysms were so like renal colic that her physician would not give up his first diagnosis, yet many of the leading symptoms were absent. She never had hæmaturia; repeated examination of the urine failed to reveal red blood-disks, pus, or anything to suggest stone or other serious disease of the kidneys.

During her four and one half years' illness she consulted eight or nine prominent physicians, and only one of them was willing to admit the possibility of a stone as the cause of the pain. I mention this to illustrate the difficulty of diagnosis in the case. Her family physician had studied her so carefully that he believed, that she had a stone in the kidney which was the cause of her illness; and sent her to me for its removal by lumbar incision. The most careful examination of the abdomen failed to give any assistance in diagnosis, and pelvic examination was also negative in its results. A thorough manipulation of the left kidney, which was rendered possible by the exceedingly lax and thin abdominal wall of the patient, did not cause any pain, the kidney could be plainly felt between the two hands and was not enlarged. There was no hæmaturia, pain, or any symptoms suggestive of stone following the examination. After her attacks of pain were over she was perfectly relieved; except an irritable bladder which followed each one, and continued two or three days afterward. The amount of urine passed in twenty-four hours was normal, and was free from casts and albumin.

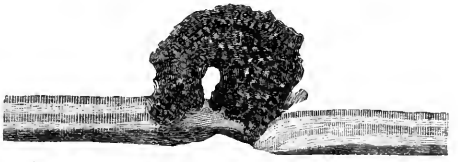
The family history was negative. After carefully considering the case I was at sea regarding a diagnosis. That the cause of the attacks of pain was located in the abdomen was evident, and that they had some connection with the left kidney or obstruction to the flow of urine through the ureter was reasonably certain, but the cause and location of this obstruction were not apparent. I was strongly inclined to the opinion that there was a stone either in the kidney or ureter, but I was not willing to make a lumbar incision when the diagnosis was so uncertain. If I should do so I would be subjecting the patient to the operation without much hope of relieving her. I therefore advised an abdominal section for diagnostic purposes, determined to be governed by what it revealed. If I detected a stone in the kidney, to remove the stone by a separate incision through the loin. I was encouraged to perform this novel operation by the confidence I possessed that a simple exploration of the peritoneal cavity was free from serious risk, and that the exploration would settle the question of diagnosis without a possibility of doubt—the very question which had been the bone of contention by the many distinguished consulting physicians preceding me. If in the exploration I should find a stone in the kidney its extraction would not be difficult by the lumbar incision after the method of Thornton. By this method we are able to grasp the kidney with the hand inside of the abdominal cavity, and hold it firmly against the loin in the most favorable position for reaching and removing the stone by the lumbar incision. These were not the only advantages to be gained by abdominal section in this case, as will be made apparent later in its history.

The patient was admitted to my "Home" for operation, which was performed September 4, 1889, at eleven o'clock. At ten A.M. the patient told me if I would wait a couple of hours I would see her in one of her paroxysms of pain, for she was certain one was coming on. At eleven o'clock she was anæsthetized by Dr. C. B. Van Meter, and with the assistance of Dr. Samuel Zurmehly, and in the presence of Drs. J. F. Baldwin and C. A. L. Reed the operation was performed. After the patient was put upon the table, she being then under the influence of chloroform, in palpating the abdomen I was surprised to find a small tumor, which appeared to be the size of a pint cup, in the region of the left kidney. I was certain that this did not exist the day before, and could not account for its presence now. I first made median abdominal section, four inches in length, and introducing my hand into the abdominal cavity I at once passed my hand to the left side and found an elongated, exceedingly thin-walled cyst, somewhat larger than the closed hand. Above this I could outline the kidney, which appeared of normal size. At the lower end of the cyst there was a groove in it, and the end overlapped its posterior attachment. In this groove I passed my finger and could feel a stone some three or more inches below the kidney.

The diagnosis was perfectly clear to me now. I had to deal with an impacted stone in the ureter. The left hand was not taken out of the abdominal cavity until the stone was removed. As the kidney appeared healthy I did not want to sacrifice it. I therefore made the lumbar incision as planned before commencing the operation for the removal of a stone from the kidney. After cut-

[1] Read at the annual meeting of the American Association of Obstetricians and Gynecologists, Philadelphia, September, 1890.

ting down to the kidney it was fixed with the left hand and incised, making an incision large enough to admit the finger. At once there was a gush of about one pint of urine. The cyst in the abdomen had now disappeared, leaving the kidney in its normal position. I could now feel the stone about two and one-half inches below the pelvis of the kidney, in place of three and one-half as it appeared before the kidney was incised. The most difficult part of the operation yet remained, that of the removal of the stone, which proved to be an exceedingly difficult task. With a pair of forceps introduced through the lumbar incision guided and aided by the hand inside of the abdominal cavity, several attempts were made to dislodge and remove the stone. It could not be grasped in the bite of the forceps without at the same time including the surrounding tissues, as could be very easily determined by the hand inside of the abdomen. Knowing as we did the exceeding thinness of the pelvis and ureter forming the collapsed sac we were very careful in our manipulation to avoid injuring that. After convincing myself that it was impossible to remove the stone through the lumbar incision without more room, and finding that I could push the stone with the ureter up toward the kidney to a limited extent, I decided to lay the kidney freely open, which I did along the convex border, leaving about half an inch of kidney tissue at either end of the organ unincised, with the intention of first removing the stone, and later the kidney if the hemorrhage could not be controlled. The kidney wound was held aside by retractors in the hands of the assistants, and after a tedious effort by invaginating the sac with the hand inside I was able to reach the stone with the handle of the scalpel and peel the tissues from it. The hemorrhage from the kidney was controlled by sponges from hot water. I dressed the wound in the loin by placing a rubber drainage-tube in the kidney. This tube was long enough to reach over the side of the bed to a bottle upon the floor, where the urine was collected from the kidney. The wound was sutured carefully around the drainage-tube. As I was not certain that I had not injured the thin sac and thus opened the peritoneal cavity from behind, the very thing I wanted to avoid when I planned the operation, I placed a glass drainage-tube in the abdominal cavity, which was removed in eighteen hours as it was not required. My patient suffered very greatly from the shock, which I attribute partly to the loss of blood. Highest pulse after she rallied was 126 and highest temperature 100.8° F. for one registration only, which was on the following day at three P.M. After that time the temperature varied from 98.5° F. to 99.5° F. After an examination of the stone, which weighed only $3\frac{7}{10}$ grains and measured $\frac{6}{16}$ inch long, $\frac{5}{16}$ inch wide, and $\frac{4}{16}$ inch thick, it was found to have a most peculiar shape, as you will observe from the



specimen here presented to you. The cut is from a photograph taken to show the slot in the stone. It is three and a half times larger than the specimen. It represents a section of a cylinder with a slot cutting one side, parallel with its long axis, to a little past the centre. One end of the stone and in the slot it is blackened from the contact with the urine. This blackened end was presenting toward the dilated portion of the ureter and kidney where it was impacted, with the narrow slot spoken of extending parallel with the ureter, making an opening about the size of the thickness of an ordinary pin, which was quite sufficient to carry off all of the urine from the kidney so long as no mucus or other solid material interfered with this small opening. But if a little mucus or any inflammatory material became deposited over this opening you can readily understand how it would close it as perfectly as a ball-valve. With the escape of urine from the kidney thus prevented we have a very satisfactory explanation of the pain, as well as the cause of the uneasy sensation before the attacks of renal colic, and their sudden termination without the passage of a stone, as well as why I did not detect the cyst the day before the operation. For it is evident that none existed except for a few hours preceding and during the attacks of pain. All of that portion of the ureter above the stone with the pelvis of the kidney would be subjected to dilatation until the pressure was strong enough to press the foreign material through the small opening, when the patient would get the sudden relief as though a stone had passed. Thus it is easily explained how the symptoms were so misleading to her physicians.

The four and one-half years the patient suffered from this malady was quite sufficient to dilate the pelvis and ureter into a great sac, as already described. We have equally as good a reason why the stone was not forced on into the bladder when we examine its shape. With its rough exterior it would be a difficult stone to pass under favorable circumstances, and when it was once impacted, with its long axis corresponding with the long axis of the ureter, the slot gave exit to the urine except when blocked by mucus or débris, and that would pass through before the pressure was long enough continued to have any effect in dislodging or driving the stone along the tube.

The stitches were removed from the abdominal wound on the seventh day. The wound was healed perfectly. On the following day the stitches were removed from the lumbar wound. For eight days the urine passed from the bladder contained small blood-clots, while that from the incised kidney remained clear.

A very interesting fact was observed in the secreting power of the incised kidney in comparison with the other organ. The drainage-tube must have been placed in such a manner as to drain nearly or quite all of the urine from the incised kidney into the bottle. For each eight ounces of urine passed from the bladder there would be about six and one half or seven ounces deposited in the bottle. It appeared that the incision in the kidney did not materially interfere with its secreting power. On the eighth day I removed the drainage-tube from the kidney wound. For four days after that it appeared as though all of the urine from the left kidney passed through the sinus. After the twelfth day only a small quantity escaped occasionally. This gradually diminished until the sixteenth day and on the twenty-first day the wound was perfectly healed. On the thirty-sixth day she went home in perfect health and has remained so to this day.

So far as I have been able to determine I cannot find a case of removal of a calculus from the ureter by the combined abdominal-lumbar operation, and but four cases of removal of a stone from the ureter by any other procedure. I find the report of a case by Dr. Cullingworth in the "Transactions" of the Pathological Society of London, 1884 and 1885, vol. xxxvi., page 278, of abdominal section and removal of stone from the ureter near the bladder; patient died fourth day. Dr. Terrey's case in which he was able to remove a stone from the ureter near the kidney by the lumbar incision only; patient recovered. The case is recorded in the *American Journal of the Medical Sciences*, vol. 97, page 579. A case by Dr. Berg, in *Centralblatt für Gynakology*, January 28, 1890. A female, sick fifteen years, who had passed about twenty small calculi. Temporary relief followed and then very severe dysuria set in. By aid of the sound, stone in the bladder was detected. The urethra was dilated, the finger introduced, and it was found that a calculus was impacted in the right ureter, the point projecting into the bladder; the bladder was opened from the vagina and the stone extracted without difficulty. And a case by Dr. A. T. Cobot, reported in the *Boston Medical and Surgical Journal*, September 11, 1890, in which he removed a stone from

the ureter two inches below the kidney by the lumbar section only; patient recovered. These cases are so different from my case that they need not be considered so far as the operative procedure is concerned. The case of Dr. Cullingworth would probably have recovered if he had at the same time extirpated the kidney on the affected side, that of Dr. Terrey was no more serious than that of removal of a stone from the kidney by the lumbar incision, while that of Berg is so different from any of the others that it has hardly no bearing upon them at all, and is only mentioned from the fact that it was a case of removal of stone from the ureter.

The case is an interesting one: 1st. On account of the great difficulty of a correct diagnosis before abdominal exploration. 2d. The ease with which a correct diagnosis was made after abdominal exploration in this heretofore troublesome and obscure case. 3d. If the case had been operated upon by the lumbar incision only, a correct diagnosis could not have been made, neither could the stone have been removed, by that method; and the patient would have recovered with a fistulous opening in the loin. 4th. It illustrates in a clear and concise manner the possibilites of the combined method of operating for extraction of calculi from the ureter.

ARISTOL IN AFFECTIONS OF THE SKIN.

By D. F. KINNIER, M.D.,

NEW YORK CITY.

EX-LECTURER ON DERMATOLOGY, COLLEGE OF PHYSICIANS AND SURGEONS, BOSTON, MASS.; LATE ASSISTANT IN DERMATOLOGY TO DR. T. CALCOTT FOX, LONDON, ENGLAND.

ALTHOUGH aristol has been before the profession but a comparatively short period of time favorable results which quite confirm those recorded by Eichhoff have been reported. It is in the treatment of cutaneous diseases that aristol has been most largely used. Aristol is a new iodine derivative of thymol, and is made by the addition of a solution of iodine in iodide of potassium to a soda solution of thymol. It is inodorous and supposed to be a non-toxic, antiseptic remedy. Aristol is of a yellowish-brown color, decomposing on exposure to light, and should be kept in opaque bottles. It is insoluble in water and alcohol, except in excess; it is also insoluble in glycerine; it is readily soluble in ether, chloroform, and the fatty oils. Olive oil is generally used when an oil is desired. I have used aristol in several cases, in most of which this drug acted very well; in a few cases its use was not beneficial. I shall record the more interesting ones:

CASE I. *Lupus Erythematosus.*—A. F——, aged twenty-eight, female. Eruption appeared several years ago, first upon the scalp in the form of disseminated vesicles, which, gradually enlarging, formed blebs filled with lymph-like fluid. Later, ulcerations developed which healed under proper treatment. About six months ago livid macules appeared on the arms, some of which ulcerated. There is at present an irregular and ragged ulceration on each arm, of moderate size, with reddened base, secreting a thick yellowish pus and emitting a foul odor. After the crusts were removed, a foul ulcerated surface presented which was dusted with aristol several times daily. The good effect of the drug was noticed in a few days, the granulations becoming healthier and more luxuriant. Later aristol-lanolin ointment (ten per cent.) was applied thrice daily and the ulcerated surfaces healed in two weeks, the cicatrix which was formed being quite flexible. The aristol did not produce any irritation or disagreeable symptoms.

CASE II. *Lupus Exulcerans Facici.*—G. H——, aged thirty, male. Has suffered from a small ulcerating lupus of the face for two years. He stated that the disease was very slow in its extension, and I accordingly adopted palliative and expectant treatment. After the crusts were removed a foul, ulcerating surface with lupus nodules was to be seen. Aristol in powder was applied for the first few days with good effect. The case is doing well under aristol ointment applied three times a day.

CASE III. *Sclerous Lupus.*—M. D——, aged thirty-five, male. Disease confined to fingers and hands. Aristol was applied in the form of powder, solution, and ointment. This treatment was continued for several days without producing any good effect on the disease. As this form of lupus is not frequently met with, a few remarks may be of importance. This is the *lupus sclereux* of French writers. Other names applied to it are *lupus verruqueuse*, *lupus verruqueux*, and *lupus verrucosus*.

Sclerous lupus may develop on any part of the body, but Vidal states that this variety of lupus is most frequently observed on the fingers, hands, toes, and feet. McCall Anderson states that its most common sites are upon the nose, cheeks, and ears. According to Vidal, sclerous lupus may develop primarily or it may be observed as a secondary phase of the transformation of a primary tubercular lupus. That the lesion is of a lupous nature is shown by the formation in the cicatrix of small, yellowish, translucent tubercles during the process of healing. Vidal, who has made sections of the infiltrated tissue in sclerous lupus, finds a superficial papillomatous layer simulating epithelioma, and constituted by exuberant epidermic proliferation; a middle layer of sclerous tissue; a deep layer in which were lupus tubercles with all their histological characteristics. According to the statistics of Dr. Vidal, this form of lupus occurs about once in eighteen cases, and more frequently in men than in women, while the commoner forms of lupus are more frequent in females.

After a thorough trial of aristol I had recourse to scraping, and with good results. The curette was used whenever any lupus tubercles were observed in the cicatrix. After scraping, aristol ointment was applied. This is the only case of sclerous lupus in which I had an opportunity of using aristol, and from my experience with it I do not think the drug will find favor in the treatment of this form of lupus. There is another form of sclerous lupus where the tubercles are superficial, subepidermic, and visible to the naked eye, presenting an indurated base and involving the entire thickness of the derma and subcutaneous cellular tissues.

I do not think aristol would produce beneficial results if used in this form, but that is no reason why its use should be deprecated in the treatment of lupus. This latter variety of sclerous lupus I have seen in Vidal's clinic I think more frequently than the first-named variety of sclerous lupus.

CASE IV. *Ulcus Varicosum.*—M. J——, aged forty-five, female. Has had varicose condition of veins of legs for several years. Has medium sized ulcer on inner side of right leg just above malleolus, surrounding tissues eczematous and tender. Aristol in powder and as ointment was used and the ulcer healed in two weeks. The eczematous condition was cured before the ulcer.

CASE V. *Psoriasis Vulgaris.*—J. P——, aged twenty-five, male. Greater part of body covered with typical psoriasis patches, those on knees and elbows appeared to be chronic in character. Aristol ointment was applied and the patches disappeared in ten days, excepting those on the knees and elbows, which were relieved in two weeks. No internal treatment was prescribed, so that the results obtained were entirely due to the use of aristol.

CASE VI. *Tinea Versicolor.*—A. E——, aged twenty, female. Large and irregular patches over chest and several isolated patches on the back of the patient. An ether solution of aristol cured the patient in a few days.

CASE VII. *Erythema Intertrigo.*—A G——, aged nine months, male. Very angry-looking eruption in the groins. Dusted with aristol and powdered acacia. Disease cured in four days.

CASE VIII.—This patient was a man with preputial chancroid near the frenum. When first seen the chancroid was touched with nitric acid and dusted with aristol.

July 7th, two days later, chancroids improving. July 9th, small chancroid on glans. July 12th, chancroids spreading; applied nitric acid and aristol. July 15th, chancroids much improved. July 22d, patient discharged cured.

CASE IX.—Patient was a man twenty-five years of age. Venereal sores on glans and inner aspect of prepuce. Induration absent. Sores superficial and covered with yellowish pus. Nitric acid and aristol applied. July 12th, three days later, ulcerated surfaces are smaller. July 15th, ulcerations appear to be spreading; pus forming rapidly and is very offensive. Burnt with nitric acid and dusted with aristol. July 20th, improving. July 25th, discharged recovered.

CASE X.—The patient is a man thirty years of age. There are two typical soft sores about the size of a small pea in the sulcus coronarius, of ten days' duration. Inguinal glands enlarged. Aristol in powder, solution, and ointment failed in this case to produce any good effect. Iodoform was substituted and the sores healed rapidly.

Aristol is useful in the treatment of ringworm, but there are more effective remedies. Good results were obtained by the use of aristol in cases of purulent otorrhœa with eczema auris. Brocq, who has had a large experience with aristol, recommends it highly as a topical application for ulcer of the leg, and with absolute rest of the limb considers the aristol treatment superior to the iodoform treatment. Aristol in varicose ulcer of the leg brings about a more rapid cicatrix than iodoform. Aristol seems to have a special action in lupus, especially the ulcerating form, and is highly recommended by Brocq and Eichhoff, the latter claiming that it acts as a specific poison to the bacillus tuberculosis of lupus.

Whether aristol will replace iodoform in the treatment of skin disease remains to be decided. Aristol has many points to commend its use over that of iodoform, one in particular being its freedom from odor.

Aristol being an iodine compound, is supposed to produce toxic symptoms, especially if applied over a large surface. This doubt may be dispelled by an examination of the urine in cases where aristol has been used. Repeated examinations of the urine by Castani's method and the starch-paste test failed to give the iodine reaction. Both these tests are delicate and reliable, and iodine, if present in only a trace, will be detected in the urine. In psoriasis aristol seemed to act well, but not so promptly as chrysarobin. There are many objections to the use of chrysarobin in the treatment of psoriasis which do not hold in the case of aristol, such as dermatitis, conjunctivitis, discoloration of the skin and clothing. Aristol is devoid of all the unpleasant symptoms and is worthy of a most careful trial in the treatment of psoriasis.

Dr. Brocq reports the case of a patient suffering from extensive superficial epithelioma of the face, which was almost entirely healed in three weeks by dusting with aristol. Aristol seems to act specially in bringing about cicatrization in obstinate ulcers, ulcerating lupus, and in superficial epithelioma. Cases of rhinitis, moist condylomata, specific ozæna, suppurating gummata, syphilis of the naso-pharynx, have been reported where the use of aristol has been followed by good results.

Eichhoff suggests its use in local tuberculosis and constitutional syphilis by hypodermic administration.

Aristol is worthy of very careful trial.

I have to express my thanks to Dr. J. M. F. Egan and Dr. D. J. Sheehan, of Harlem, who have kindly placed at my disposal several cases, in order to carry out experiments with aristol.

Medical Students in London have been compelled to go through a course of four years' study, hospital attendance, and lectures before being qualified to appear for the final examination. By an order of the General Medical Council of England, issued last month, the term of preparation has been now extended to five years.

CATARACT EXTRACTION.[1]

By BARTON PITTS, M.D.,

PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY, ENSWORTH MEDICAL COLLEGE, ST. JOSEPH, MO.

I SHALL not attempt a description of the many different kinds of cataracts, nor the various operations which from time to time have been proposed for their relief. Such information may be found accurately and systematically set forth in any of the modern text-books upon the subject. My remarks I shall confine to the consideration of the two methods of extraction—with and without iridectomy. In the premises I will state that I do not essay the position of a partisan of either particular method of operating, and that in this day of extensive and accurate statistics it would be presumptuous to attempt to be dogmatic.

The time has not come, nor will it ever come, when there will be one universal method of extracting cataracts. Anatomical and pathological conditions, to say nothing of individual fancies and prejudices on the part of operators, will preclude the possibility or advisability of the adoption of any one method of procedure. Since, in the use of antiseptics, the former great danger of septic infection of the eye, often destroying the effect of the most skilfully and carefully performed operation, is removed, the prime effort of the advanced operators of the present day is to obtain the maximum results of the object for which the operation is performed. Such a desideratum I would define as the most perfect restoration of vision with the least deformity, attainable, of course, with the least danger.

In the judgment of the prudent, even a moderate and useful degree of success is preferred to the possibility of a more brilliant result attainable by more hazardous methods. In contrasting, therefore, the two operations of the day—the one in which extraction is accomplished with iridectomy, the other without—not only the attainable visual result, and the cosmetic appearance of the eye is to be considered, but the relative degree of danger and the difficulties of performance are important factors.

It goes without saying that, other things being equal, an eye operated upon for cataract without iridectomy possesses more useful and more comfortable vision, and has the additional recommendation of leaving the external appearance of the eye unmutilated, which, in many instances, is a matter of considerable moment. As to the relative degree of danger and difficulty of the two procedures I am as yet somewhat undecided. From my own experience I am satisfied that the technique of the simple method of extraction, without iridectomy, is the more difficult of performance, even at the hands of one who may be very experienced and skilful. As every operator has to acquire knowledge, to a certain extent, not only by the experience of others, but by individual difficulties, mistakes, and failures, this I think an argument against the general acceptance of this method of operating.

The additional difficulty of performance, however, is no argument against the merits of the operation; for if it gives better visual results, and is equally safe, its adoption is assured at the hands of those who feel competent to undertake its performance. The reasons which in the course of my experience convince me of the greater difficulty of the operation without iridectomy are as follows: In the incision in the cornea the wound must be at a considerable distance from the sclero-corneal junction in order to afford room for the iris in delivery of the lens, consequently the lens has to subtend a greater distance and undergo a greater displacement in its exit than if the incision were nearer the same plane of direction of the lens; another, and to me the greatest difficulty encountered, is the interposition of the iris, which not only occupies a certain portion of the too-limited space, but by its contraction, invariably following upon

[1] Read before the Missouri State Medical Society, May 6, 1890.

evacuation of the aqueous, despite the previous use of atropia, offers a direct and forcible resistance to the escape of the lens. It is true that by manipulation and properly directed force this difficulty may be overcome. Such efforts in my earlier attempts, however, were productive of laceration and more or less bruising of the iris, and in one instance was attended by so much difficulty that, to avoid the danger of undue force, iridectomy was resorted to, although not previously contemplated, whereupon delivery was greatly facilitated.

To overcome this difficulty of the resistance of the iris, and to avoid laceration and bruising of its surface, I have of late resorted to making the corneal section much farther from the sclera than in the Gräfe method with iridectomy, thus leaving ample space for the iris between its base and the point of exit of the lens through the cornea, into which it may be crowded. In several of my earlier extractions without iridectomy, owing to the nearness of the corneal section to the scleral margin, I found, upon attempting delivery of the lens, there was not sufficient space for the iris to occupy, and not only great difficulty was encountered but injury to the iris ensued, followed by more or less iritis, with slight incarceration of a portion of the iris in the corneal wound in healing; thus defeating one of the prime objects of the operation, rotundity and mobility of the pupil. Several expedients have been proposed to overcome the difficulty of the delivery of the lens, and for the additional purpose of protection to the surface of the iris.

By Dr. Valk a distensible shield, pointed with two knobs, is proposed. The method of its manipulation is to insert through the corneal wound, cover the surface of the iris, and by the knobs holding in the pupil, retract the iris upward as far as necessary and slide the lens over the front surface of the shield. Dr. Valk reports good success with it. I have not tried it, nor am I familiar with its pattern except from description. I should think, however, it objectionable on the score of occupying considerable space, already too limited. Its insertion, moreover, I should think awkward, and in the event of sudden movement of the eye under operation its presence in the anterior chamber especially dangerous. The expedient I have resorted to, in order to overcome the presence of the iris and to protect it from injury, is, after obtaining the maximum effect of a strong solution of atropia and cocaine, to make the corneal wound well forward at its apex, beginning very near the sclero-corneal junction, about one-third of the distance below, cutting upward and outward, terminating at a considerable distance from the periphery of the cornea above. By this slanting direction of the corneal wound a greater length of section is obtained than in beginning the section farther forward in the cornea, and space available is left between the upper flap and the sclera for the body of the iris. I use, in making the section, the large sized Gräfe knife. To overcome the resistance of the iris, and frequently rigidity of the pupil, I have for two years resorted to the same instrument recently mentioned by Dr. Knapp as used by him, that is, a fine wire loop attached to a delicate handle. This instrument, which can be easily and thoroughly sterilized, I insinuate through the corneal wound into the pupillary space, and retract the iris into the superior triangular space, and by a gentle pressure backward and upward of a strabismus hook applied against the lower edge of the cornea, I have little difficulty in the delivery of the lens, and without material injury to the iris, and in no instance accompanied by loss of a single drop of vitreous or followed by a septic infection of the eye.

Rupture of the capsule I prefer, after corneal section, and give preference to a horizontal incision as near the upper edge of the lens as practicable. After delivery of the lens, in case of prolapse of the iris, I replace as carefully as possible, usually with the before-mentioned wire loop, using a strong solution of atropia to maintain dilatation of the pupil, in preference to eserine to contract it, there being less danger, in my opinion, of prolapse and less liability to anterior synechia of the iris when dilated than when contracted, that is, with the corneal wound lying well forward.

In the event of the iris being much bruised and difficult of reduction and retention, as happened in one of my operations upon an aged patient, in whom the iris was in an atrophic diseased condition, I should, as I did in this instance, perform a precautionary iridectomy, even after safe delivery of the lens. In a healthy condition of the iris, however, a considerable amount of manipulation is well borne, and I have found that by waiting a short time reduction and retention may be often more easily accomplished than immediately. Should slight prolapse or incarceration of the iris take place, serious consequences, under my observation, need not necessarily ensue. Several such cases I have had, accessible to inspection from one to four years, and one case, in which incarceration of the iris was present, dated back ten years, and with the exception of more or less loss of mobility and rotundity of the pupil, no evil consequences have occurred. This manipulation of the iris and introduction of instruments into the chamber of the eye must, I think, be always attended with a certain amount of danger, and offers a more or less reasonable objection to the simple method of extraction; but it must be borne in mind that under strict antiseptic precautions and skilful manipulation all these dangers and difficulties may be overcome and most brilliant and useful results obtained. In the old method of Gräfe, in vogue for the past two decades, the corneal section lies much nearer the sclera, and consequently more nearly in the plane of the direction of the lens, but leaves no space as provision for the iris. Iridectomy is therefore imperative. The ease with which delivery of the lens and cortex is accomplished in this method of operating, avoiding the danger of undue force and manipulation; the avoidance of prolapse and incarceration of the iris; the infrequency of posterior synechia and obliteration of the artificial pupil; and the crowning glory of the large aggregate of statistics for the past twenty years, showing a percentage of successes, at the hands of different operators, ranging from eighty to ninety-five per cent., must maintain the popularity of this method of operating for cataract as a favorite procedure for many years to come.

In fact there are conditions often present in cataract extraction, such as an exceedingly small cornea, shallow anterior chamber, a diseased condition of the iris, fluidity of the vitreous, and other unusual conditions and complications which must at times debar the simple method and give permanency to the method of extraction with iridectomy. In considering the relative degree of danger of corneal suppuration, plastic iritis, and panophthalmitis in the two methods of operating, I believe, since the advent of antiseptics, there is no greater risk in the one than in the other. The liability of prolapse and incarceration of the iris is greater in the simple method, but, when skilfully performed and confined to properly selected cases, need not occur, and, in the event of occurring, is not necessarily a matter of serious consequence. In cases of fluidity of the vitreous I am not prepared to claim superiority, as to safety, for the simple method of extraction. In my experience in extraction of cataract, both with and without iridectomy, it has been my fortune never to have encountered an instance in which the vitreous was in a fluid state. In a normal condition of the vitreous I think there is little occasion for apprehension as to escape of the humor in either method.

When in a fluid condition, however, I am inclined to feel that in extraction with iridectomy there is less danger of escape than by the simple method. It is true that in extraction with iridectomy the corneal incision lies nearer the posterior chamber and invites escape of vitreous during and after operation more than if at a greater distance; and, again, in an iridectomy a breach in the continuity of the iris is established, thus doing away with a certain

amount of support and resistance offered by that membrane. On the other hand, I think the increased manipulation, force, and pressure required for delivery of the lens without an iridectomy are more conducive to escape of the vitreous, particularly at the time of operation, than with it.

Another objection to the method of operating without an iridectomy which has presented itself to me in several instances is the difficulty of thoroughly removing the *débris* of the lens.

The corneal incision lying so far forward, a ready exit of fragments of the lens cannot be accomplished, and, moreover, the undivided circular form of the iris offers, as it were, a hiding-place for small bits of cortex and broken fragments of the lens.

Of late I have not hesitated, however, in freely irrigating the anterior chamber, detaching and washing out all remnants of the cataract, using for this purpose a warm solution of 1 to 20,000 of bichloride of mercury in distilled French rose-water. My method of irrigating the anterior chamber is as follows: After drawing out to a fine point a small glass tube, I insert it in one end of a piece of flexible rubber tubing, thoroughly sterilized, suck up by the mouth the tube one-half or two thirds full of the bichloride solution, and by the force of the mouth perfect control may be exercised over the force of the current in washing out the anterior chamber, leaving both hands free for manipulation—one for directing the glass tip, the other for controlling the eye, or other necessary movements. As yet I have seen no undue irritation or inflammation follow upon the use of this solution or method of using it. In this procedure of irrigation of the anterior chamber we possess, I think, a means of safely operating upon cataracts heretofore considered unripe on account of the cortex being unsolidified, and the difficulty of removing *en masse* the entire contents of the capsule deterring earlier operation. As an important plea for early removal of the cataractous lens, after useful sight is lost, in addition to the relief of mental distress, and the joys of an earlier restoration of vision, I am convinced that the conditions are more favorable for success the earlier the operation. In nearly all cases of long-standing cataract, in the aged especially, there is an atrophic, friable state of the iris, probably due in great measure to the continued presence of the diseased lens. Thickening and opacity of the anterior capsule are also more frequent in long-standing cases of cataract.

As to the claim for the procedure of iridectomy as a precautionary measure against iritis, I am by no means agreed. In the event of septic infection of the eye, resulting in plastic iritis, there is, I think, less likelihood of obliteration of the pupil with an iridectomy than without; under antiseptic precautions, however, there is no occasion to anticipate such a condition, unless in exceptional instances, such as accidental infection, complication of dacrocystitis, etc.

As to the liability of originating iritis, I think the greater danger lies in the mutilation of the iris by an iridectomy than without it, provided the iris be uninjured or materially so, in the extraction of the lens. As to the relative position and shape of the corneal wound in the question of healing, I think there is practically no preference. The liability of the corneal wound to gape arises, I think, in the great majority of instances, from pressure applied in bandaging the eye after operation. The lid I consider the best and only bandage necessary, so far as support to the cornea is concerned. I usually apply a thin film of absorbent cotton, saturated with a strong solution of bichloride of mercury, over the lids, and adjust a light quantity of antiseptic cotton upon this, held in position by a very loose bandage, consisting of a small square piece of linen, with four strings attached, for tying loosely behind the head, which permits of frequent inspection, several times daily, from the hour of operation.

In conclusion, I shall briefly refer to the results, as to vision, obtained by the two different methods of operation.

Owing to want of care in preserving tabular records in practice, I am not prepared to offer accurate and detailed reports of my cases.

I can only report general conclusions that in upward of one hundred cases, about one-fourth of which have been performed without iridectomy, in none have I met with corneal suppuration, plastic iritis, or panophthalmitis in either procedure. In two instances the result as to vision was nugatory. One failure occurred while operating with, the other without, iridectomy. In neither instance, however, was the failure to restore sight attributable to the method of operating, nor to complications arising therefrom. In one case there was neuritis, and in the other chronic irido-choroiditis, existing prior to operating, and in neither case was there more than a trace of quantitative perception of light before operation. So hopeless was the outlook for benefit, that in both instances operation was done under protest, and simply as a gratification to the individuals at the solicitation of friends.

Such failure, therefore, to produce sight in instances of so marked, grave complications, should not legitimately be included in statistics showing the attainable results of cataract extraction.

In every other instance good vision was obtained by both methods, sight ranging from $\frac{xx}{10}$ to $\frac{xx}{20}$, and in one instance $\frac{xx}{15}$, being prevented often by circumstances incident to private practice, as well as negligence, from keeping accurate records of the visual results obtained, particularly the ultimate effect. I am not in a position, individually, to contrast the results, as to vision, between the two methods. In one of my cases, after removal of the cataract without iridectomy, and obtaining a round, active pupil, and healing without complications, a phenomenon of rather a puzzling nature remained.

Six days after operating, November 15, 1888, upon the right eye V. + 10 D. $= \frac{xx}{15}$. September, 1889, V. + 11 D. $= \frac{xx}{60}$. March, 1890, V. + 11 D. = cl. + 1 ax. 90° $= \frac{xx}{30}$.

There was inability, however, to wear the above lens owing to its marked magnifying effect upon the size of the object, and the consequent difficulty experienced in measuring distance and locating the position of objects. Even the reduction of one-third the full strength of the lens could not be used in locomotion, and after one-half reduction complaint of slight enlargement of objects persisted.

I am at a loss to account for the condition, unless it be attributable to the psychological function. That it is due to the method of extraction is, of course, untenable.

Dr. H. Knapp, in reporting two series of one hundred cases each of cataract extraction without iridectomy, gives tabular statistics showing in the first series ninety-six per cent. of good results, three per cent. moderate, and one per cent. failure. In the second series, ninety-seven per cent. good vision; two per cent. moderate; one per cent. failure, and in this series, by subsequent discission operations, restoring three-fifths of possible maximum sight, including extraneous complications. Such results as these, while not attainable at the hands of the average surgeon, cannot be paralleled as yet by any other method, and show beyond argument the merits and safety of the procedure of extraction without iridectomy. In conclusion, to summarize, I believe the operation of extraction without iridectomy is always more difficult of performance than with an iridectomy, yet in the great majority of cases it is practicable, safe, and approaches more nearly to the ideal in results, as to vision and appearance.

New York Polyclinic.— The catalogue of the New York Polyclinic shows an attendance for the session of 1889–90, of 422. The Faculty have resolved to exclude all but graduates of regular medical colleges from matriculating at this school.

Clinical Department.

COMPOUND COMMINUTED FRACTURE OF THE PATELLA.[1]

By H. L. JENCKES, M.D.,

HAZEL GREEN, WIS.

EVEN a casual perusal of the literature of this subject leaves the impression that no uniform rule of treatment is, at present, agreed upon.

Prior to the advent of antiseptics there was one general opinion regarding the results of treatment of this fracture; the object being to secure a short and firm ligamentous union of the fragments.

Of late, however, many attempts have been made to secure bony union, by wiring together the fragments. All are familiar with the opinion expressed by the Société de Chirurgie, of Paris, regarding operative treatment in this class of fractures. The members, with few exceptions, looked unfavorably upon the procedure.

Hamilton[2] was of the opinion that a short, strong, fibrous union gave nearly, perhaps quite, as serviceable a joint as did bony union.

Dr. William F. Fluhre, in quite a long and exhaustive article, which recently appeared in the MEDICAL RECORD,[3] strongly advocates the wiring of the fragments, even in recent simple fracture of this bone. He says: "The non-operative treatment, it appears to me, should be restricted to those cases of fracture in which there can be obtained either bony union, or a short, inextensible ligamentous union. The interior conditions of the joint essential to the production of this result are present in only a small minority of cases." This would bring nearly all cases of fracture of the patella in the class requiring operative treatment.

As considerably opposed to this opinion are the views expressed by Dr. William T. Bull,[4] who says: "Although my experience has been limited in recent fractures to the simplest conservative treatment, it will not be out of place for me to offer some criticisms on the more severe operative procedures, which have attracted so much attention. First, of wiring the patella, it is needless to say that, while it made its entrance into practice by the advocacy of the pioneeer of antiseptic surgery, Sir Joseph Lister, it has never received general support. One does not need to quote the discussions of the French Société de Chirurgie, or the Medical Society of London, where the majority of speakers opposed it; nor to be familiar with the collection of statistics which speak against it. It is sufficient to know that death and disaster from amputation, and suppuration, and anchylosis have followed its performance in the hands of the many, and that we have no evidence that when in the hands of the few it has proven safe, the ultimate results have been better than those by non-operative methods."

In the discussion which followed the reading of this paper before the New York Academy of Medicine, the majority of speakers were in favor of treating simple recent fractures of this bone by non-operative methods; reserving the operation of wiring to cases of compound fractures.

It is to a fracture of this nature, treated by the non-operative method, to which I would call your attention.

On the evening of March 8, 1889, Mr. D——, a tall, powerfully built man, was kicked in the left knee by a sharply-shod horse. I saw him about an hour after the accident, and found a wound about an inch in length over the centre of the patella; this wound extended down through the fragments of the patella, but did not seem to penetrate into the interior of the joint. The three fragments into which the bone was broken were freely movable, the upper fragment being separated from the lower fragments by nearly an inch. The patient was informed of the serious nature of the accident, and was told that wiring of the fragments might have to be resorted to. The wound was first thoroughly cleansed by a warm bichloride solution. The fragments of bone and the edges of the wound were brought together and held in position by the fingers of an assistant. Adhesive strips were then applied for the double purpose of steadying the fragments and of keeping the wound from gaping. A long, well-padded posterior splint was applied; this, with a roller bandage and an ice-cap to knee, completed the dressing. The case progressed favorably, presenting no unusual feature. In six weeks the splint was removed, the patella fragments were closely united, but motion of the joint seemed gone. Friction and slight passive motion of the joint were practised twice daily, and the patient allowed to move about his room. With exercise the function of the joint gradually returned, and at present writing, a year and a half after the accident, the leg can be flexed to about ninety degrees.

The fortunate result of this case is particularly gratifying, inasmuch as only the simplest and most conservative methods were employed.

There are, however, cases of this nature which seem to immediately demand operative interference. Cases in which the fibro-periosteal investment of the bone is so much lacerated as to permit the escape of a quantity of blood into the interior of the joint. In such cases let the joint be freely opened, the clots washed out, and the fragments wired. All this to be done under antiseptic rules, and we may reasonably hope to save a limb, or to restore the function to a joint, which under the non-operative treatment might end in suppuration, anchylosis, or even in the death of the patient. Such a case is reported in the *American Journal of the Medical Sciences* for April, 1890, by Dr. Michel, of Charleston, S. C. The case was associated with hæmarthroidal effusion and extravasation to an inordinate extent. In commenting upon such cases he says: "There was a time when the fatality of such complicated fractures of this bone led to the amputation of the limb without hesitation, and in military surgery our recent experience taught us, both in field and hospital service, that under any mode of treatment then in practice, death sooner or later was certain to result, unless resort was had at once to amputation or resection."

These remarks illustrate the serious nature of compound comminuted fractures of this bone.

In summarizing our conclusions regarding the proper treatment of fractures of this bone, we would unhesitatingly oppose operative interference in recent simple fractures.

In compound comminuted fractures, in which the fibro-periosteal investment is but slightly lacerated, and hæmarthroidal effusion into the interior of the joint does not occur, we can obtain a successful result by the simplest and most conservative treatment.

We would reserve the operation of wiring to cases of old ununited fracture, and to cases of compound comminuted fracture associated with laceration of the periosteal investment of the bone, and effusion of blood and serum into the joint.

THE TREATMENT OF TONSILLITIS BY VERATRUM VIRIDE.

By W. WASHBURN, M.D.,

NEW YORK.

AN article in the MEDICAL RECORD of September 28th, by Dr. A. S. Hudson, on rapid cure of tonsillitis, prompts me to give the history of a similar case of mine treated the past week. The patient had frequently suffered from ulcerative tonsillitis, and the tonsils were now much swollen, enlarged, and inflamed. Not being satisfied with my results in former cases of this kind, I deter-

mined to try the veratrum viride treatment, and gave five drops of the tincture every three hours until three doses were taken, and no more until morning; fifteen grains of Dover's powder at bedtime. There was no soreness of tonsils remaining, but the patient took two more doses in the morning before I saw her. The pulse being weak and the patient complaining of faintness, she was confined to bed during the day, and ordered morphia one-eighth grain every three hours and a little stimulant. The faintness soon disappeared, and the tonsillitis did not cause any further trouble.

In this case the experience of Dr. Hudson was verified to the satisfaction of both my patient and myself. I would like to emphasize the necessity of using the morphia, not alone for its effect on the disease, but because of its influence in supporting the heart's action. Indeed, I believe it will be found chiefly useful on this account, because the veratrum cannot well be borne in sufficiently large doses to cure the disease without the heart receiving this support.

Progress of Medical Science.

Diphtheria and Manure. — The connection between human diphtheria and cognate maladies of the lower animal creation has now been placed on so firm a basis that it is but a step further to postulate an association between this disease and manurial refuse. Dr. Airy, in a recent report to the Local Government Board on an outbreak of diphtheria in the Samford Rural Sanitary District of Suffolk, has shown that in a particular village in this district the outbreak was immediately preceded by the passage through it of a cartload of London manure landed from a barge near by. Several children returning home from school complained of the stench from the cart and sickened soon after. These cases set others going and the disease was then disseminated by school attendance and the like. Though, as Dr. Airy suggests, the foul effluvia of the manure may have acted by hastening the growth of the diphtheria only, yet he considers some weight should be given to the suggestion that the earlier cases were, in some way or other, due to the introduction of the manure. He states that the traffic in manure has increased greatly in these parts of late, and points to the great increase of diphtheria in London since 1882. Dr. Airy's suspicions as to the ability of manure to convey disease are confirmed by the medical officer of health, Dr. Elliston, who has observed scarlet fever to develope in certain places after the deposit of London manure. Similar experience is also forthcoming from Strood, in Kent. The whole question of this association between infectious disease and manurial refuse deserves the attention of sanitary workers and observers. Whether the association is one of coincidence only or is truly causative, extended inquiry alone can determine; and if the latter be the case, it will yet have to be said whether the infection is a direct one, that is, whether the poison contained in the manure is derived from a toxic animal's discharge or secretion; or whether the infecting manure acts only as a *nidus* or multiplying ground for the resting forms of certain specific contagia which may gain access to it. We trust that all who have opportunity of observation will not fail to record any facts bearing on this highly important and interesting problem.—*Medical Press.*

Action of Urine on Tissues.—This subject was recently discussed before the Société de Biologie. The older surgeons considered infiltration of urine as a grave accident, particularly in preventing the union or cicatrizing of wounds. This opinion is erroneous in more than one point, as the clinic daily demonstrates the negative. On the other hand experimental researches of Guyon and Buchard have shown that urine alone is aseptic. That it becomes hurtful after alteration, due to the accidental development and multiplication of the pyogenic bacillus which gives the urine irritating properties, ramified in certain cases by gangrenous and diffuse phlegmons. In his turn M. Tuffier, in experimenting upon animals, has once more confirmed the views now all but universally admitted. They fully support some recent surgical operations that seem bold to the point of rashness, such as the resection of the vesicle wall for neoplasm, etc. Genito-urinary surgery is, like other branches, dependent largely upon experimental work for its further advancement.—*The Journal of the American Medical Association.*

Failure of the Suspension Treatment of Locomotor Ataxy.—There are signs in the air that the suspension treatment of progressive locomotor ataxy, respecting the beneficial result of which we have heard so much during the last year or two, is likely to follow Bergeon's recto-insufflation treatment and Apostoli's electrical treatment for uterine fibroids. The ease with which trained observers become convinced of the value of a method which subsequent experience shows to be idle, if not injurious, is really marvellous, and points to certain defects in the constitution of the individual mind. The great point, to begin with, is to establish indubitably the nature of the disease which it is proposed to cure, and this is often not possible, or, if possible, is rarely accomplished. Both operator and subject, moreover, seem to be hypnotized by the concentration of the attention on a given object, and the result is an amelioration which, in the hands of less enthusiastic observers, is frequently conspicuous by its absence. These medico-historical facts should teach us to show a becoming diffidence in placing too implicit confidence in new remedies. Who will venture to assert that a time will not come when the panaceal qualities of antipyrin will have sunk into oblivion (though not without having made the fortunes of a number of speculators), crushed by the pretensions of new derivatives from other series at present unknown to the chemical and therapeutic world.—*Hospital Gazette.*

Mercurial Treatment of Dysentery.—Dr. Lemoine has had an opportunity to treat 102 cases of dysentery in the military hospital of Oran. Fifty-four were treated with sublimate clysters, being those who could not take calomel owing to some disturbance of the stomach. Twenty-one used calomel, with a beginning dose of 1 gramme followed in the next two or three days by smaller doses; 11 were treated with ipecacuanha; and 16 in the beginning with ipecacuanha, and later with mercury. No deaths were noted, and ordinarily 1 gramme of calomel was sufficient to check the slimy and bloody stools. In 28 of the cases, the favorable results were immediate. The clysters, consisting of 200 grammes of a five per cent. solution, were commonly retained about ten minutes, and worked rapid improvement in the tenesmus and slimy discharges. In some cases, owing to the sensitiveness of the anus, it had to be painted with a solution of cocaine. In many cases the calomel was given in connection with the clysters. Poisonous symptoms were not noted in any case. The author refers the favorable action of mercury in these cases to its antiseptic power.

Doctor and Preacher.—The following epigram on a well-known physician and preacher has been going the rounds again:

"*Omne tulit punctum qui miscuit utile dulci.*"

Parson and Doctor joined in one
Most suitably we find;
The one the suffering body treats,
The other soothes the mind.
The Parson shows the way to heaven;
And then, with tender care,
The Doctor consummates the work,
And gets the patients there.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, October 18, 1890.

THE OFFICIAL REPORT OF THE EXECUTION BY ELECTRICITY.

DR. CARLOS F. MACDONALD, State Commissioner of Lunacy and Chairman of the Medical Commission of Experts in the Kemmler execution, has made an official report to Governor Hill, in which he declares himself in favor of the new law. It will be evident, to such as read his statements and note his comments, that the strongest possible argument has been offered for the electrical method of getting rid of criminals. With the firm conviction that he is in the right, he has conscientiously stated the truth as he sees it, and his conclusions are to be respected accordingly. While in some respects we cannot agree with the distinguished commissioner, every one present at the execution must admit that, whatever of failure there was in the execution, no possible reflection can be cast upon his endeavors to make it a success. That it failed in spite of his best efforts to the contrary, is the most severe criticism that can be offered against the method. The part which he took in the matter of advising and directing was certainly beyond criticism. From his stand-point everything was done which was possible in order to take advantage of all the experience gained in studying the subject from a practical as well as theoretical standard. In our opinion the execution was a failure, notwithstanding. Whether the victim was absolutely dead or not after the first stroke, will perhaps ever be an open question. The necessity of applying a second stroke is the strong element in favor of the doubt. There is great satisfaction in knowing that after the first stroke consciousness was abolished, and the culprit did not actually suffer. But it was quite hard to kill him, nevertheless. In the light of present experience it is a pity that the time of the first shock was not lengthened to twenty seconds, as originally recommended by Dr. MacDonald; then, as he suggestively admits, there would probably have been no grounds for adverse criticism. The time of the second current was unnecessarily long, as Dr. MacDonald very properly states. As a result of an exhaustive study of the subject in all its details, he concludes his report with the following suggestions, which are worthy of the most respectful consideration:

"1. The statute providing for the execution of criminals by electricity should be amended so as to provide for but one plant, to be situated in the central part of the State, in a building especially constructed for the purpose. The building should contain the necessary electrical apparatus, an engine, execution-room, solitary cells, and quarters for the guards and other necessary officials; the apparatus to be in charge of, and operated by, a competent, accredited electrician.

"2. The engine and dynamo should be especially constructed for the purpose, and should be capable of generating an electro-motive force of at least 3,000 volts, in order to insure the maximum voltage that would be necessary, and at the same time cause no injustice to any electrical lighting company, such as is likely to be the case so long as commercial dynamos are used in executing criminals.

"3. The volt meter should be placed in the execution-room, and a competent and responsible official should be detailed to take the readings of the meter before and at the instant the current is applied. The voltage should not be less than 1,500 nor more than 2,000, and should be a matter of official record. The prisoner's resistance should also be taken immediately before bringing him into the execution room.

"4. The statute should require an official report of each execution, to be made to the Governor within ten days after the execution takes place."

DERMATOLOGICAL INSTRUCTION IN AMERICA.

THE tendency of modern medicine to the creation of specialties must be recognized as an important element of progress. The division of labor, upon which the idea of specialism is based, is a necessary condition of success in a field so broad as that of medicine. The concentration of effort within certain limits results in a more exact knowledge, a more thorough acquaintance with detail, and a higher quality of skill. In perfecting particular parts or branches of medicine, specialism contributes to the perfection of the whole.

There is no doubt that the number of medical men who devote themselves to specialties is rapidly increasing. Many are attracted to a special line of study by the intrinsic interest of the subject, while others embrace a specialty solely from its presumed material advantages. To the average medical mind a special practice presents many alluring and seductive phases. It means an exclusive office practice, regular hours, higher fees, with a comparative exemption from the arduous outdoor duties of general practice.

But the multiplication of specialists threatens to be an abuse. The Austrian Government has recognized this fact, and, it is stated, will shortly issue an order for the regulation of special medical practice by prohibiting anyone to practise as a specialist in any particular branch of practice who cannot give proof of having specially studied the class of diseases he proposes to treat.

The title of specialist carries with it a presumption of special study, of superior knowledge, of a higher degree of skill in the treatment of a particular class of diseases; but if measured by this standard it must be admitted that many specialists will be found sadly lacking. Too often the young medical man sets up as a specialist immediately after graduation, with no opportunity for spe-

cial training than that afforded by the ordinary curriculum of the medical college. Unfortunately, few of our medical schools afford either the time, opportunity, or facilities for acquiring a thorough knowledge of special studies.

In his recent address before the American Dermatological Association, the President, Dr. Prince A. Morrow, after referring to the extraordinary growth and development of American dermatology, and the brilliant record of its scientific work, considers the present position of dermatological instruction in this country. He calls attention to the general recognition of the importance of a knowledge of skin diseases as an essential element of medical education, and the extraordinary increase of the teaching facilities in this branch of medicine.

Previous to 1876, the date of organization of the Association, there were but twelve medical schools in this country in which instruction was given in diseases of the skin, and the entire teaching capacity was represented by 3 professors, 2 clinical professors, 5 lecturers, and 2 instructors. With the view of obtaining facts which should serve as a basis for an exact appreciation of the provisions made by the different medical schools for instruction in dermatology, a circular letter was addressed to the executive officers of more than one hundred medical colleges in the United States, requesting a copy of the announcement and information as to the hospital and dispensary facilities for the clinical teaching of skin and venereal diseases.

An analysis of the facts thus obtained shows that no fewer than seventy-five medical colleges have officially recognized representatives of dermatology in their teaching faculties, ranked as follows: 49 professors, 8 clinical professors, 22 lecturers, 7 instructors, with a large number of chiefs of service and clinical assistants who, in many instances, give instruction. In the department of venereal and genito-urinary diseases there were 24 professors, 4 clinical professors, 6 lecturers, and 6 instructors. Leaving these aside there is found an increase in the number of teachers of dermatology from 12 to 86.

The inquiry is then made whether the methods of instruction as now conducted, and the clinical facilities as now organized, in many of our medical schools, conduce to the cultivation of a sound knowledge of dermatology; whether the student is fitted by a thorough practical training for the ready recognition and the intelligent management of cutaneous diseases when met with in practice. "Does this extraordinary increase in the teaching organization denote a healthy and substantial progress, or is it a mere mushroom growth, delusive alike in its aspect of vitality and its promise of usefulness?"

Notwithstanding this numerous and imposing professional array, Dr. Morrow is not disposed to take an optimistic view of the situation. He asserts that an examination into the practical results of the present system demonstrates its defects. The majority of graduates in medicine are launched into practice with the merest superficiality of knowledge, often in complete ignorance of the most elementary principles of cutaneous medicine.

For the successful teaching of diseases of the skin two conditions are essentially requisite: 1. Capacity of the instructor. 2. An abundance and variety of clinical material. Without criticising the competence of the instructors, he asserts that the second most essential condition of the successful teaching of the treatment of skin diseases is sadly lacking; the majority of our medical colleges are absolutely unprovided with adequate means for clinical instruction.

Even in our large centres of population, where clinical material is abundant, its advantages are too often dissipated by its division and diversion into many separate classes. Instead of patients being aggregated into one or more large central establishments where they may be available for purposes of clinical instruction, they are dispersed in small groups here and there in various dispensaries. Another drawback to efficient instruction is the lack of special hospitals and special wards in general hospitals for this class of patients. For the education of the student in the diagnosis and treatment of skin diseases bedside instruction is essential; in no other way can the practical requirements of clinical teaching be realized.

Other existing defects in the organization of dermatological instruction are directly referable to the governing faculties of the colleges.

1. The lack of system and proper grading in the order of studies.

2. The insufficient time and opportunity afforded for special studies, the schedule being so arranged that the student's time is almost entirely occupied with those studies which are deemed essential to graduation.

3. The most serious obstacle to proper instruction in dermatology is the attitude of the governing faculties toward special studies, in ignoring them as a necessary part of medical education. There is no medical school in this country in which the study of diseases of the skin is obligatory; in none is a knowledge of this important branch of medicine required as a condition of graduation; the professor in this department is not allowed to interrogate students, and has no voice in deciding upon their qualifications for a degree.

Until the attitude of the governing faculties of the medical schools toward special studies undergoes a radical change, until the important and neglected branch of dermatology is rescued from its inferior position and made an integral and necessary part of the course of medical education, it is vain to expect that the student will attain that proficiency in the knowledge of skin diseases—that scientific and practical training—which the needs of his professional work demand. Unless the deficiencies in the present methods of dermatological instruction are corrected, it becomes a question whether this phase of medical education, as well as the study of other special subjects, should not be intrusted to post-graduate schools, which are springing up everywhere in recognition of existing defects in undergraduate schools. It is also a proper subject for consideration whether this post graduate instruction may not be better and more efficiently carried out under the auspices and direct supervision of the medical colleges rather than by independent organizations over which they have no control.

THE MURDER OF AN ASYLUM PHYSICIAN.

A SHOCKING murder occurred at the Flatbush Insane Asylum last week. A lunatic, who had formerly been an inmate of the asylum, entered the office in which Dr.

George W. Lloyd, the Assistant Superintendent, was sitting. After a few crazy words he fired at Dr. Lloyd, instantly killing him.

The lunatic had made himself notorious some years ago by his pursuit of the actress, Mary Anderson. He had been an inmate of Flatbush Asylum, but escaped about six weeks ago. On September 26th, he appeared at the asylum and threatened to shoot Dr. Fleming. He was allowed to depart. The authorities of the asylum are severely criticised for their negligence in thus permitting a crazy man to be at large. There seems to be good ground for such criticism and censure.

The daily press, which is so keen on this point now, however, has always systematically nourished a sentiment against putting any person in an asylum unless he or she was most pronouncedly and violently insane.

Not long ago a young woman, who suffered from the same form of insanity as that of the murderer of Dr. Lloyd, was pronounced insane by examining physicians. But a sheriff's jury decided that she was sane, and she was discharged with the acclamations of the press. Fortunately she did not kill anyone.

The Flatbush Asylum case is a most unhappy one, leading as it did to the untimely death of a most promising young man.

CONCUSSION OF THE SPINE.

About many subjects in medicine and surgery there lingers much indefinite knowledge. It is partly tradition handed down from one generation and one author to another, and yet it is not thrown aside because of a lack of anything more definite to take its place. It is therefore an agreeable task to chronicle an advance in positive knowledge. In no class of injuries has this been more needed than in those of so-called "concussion." Hitherto the views of Erichsen and Page have been authority, and they undoubtedly contain much that is fundamental and generally admitted to be true. It has been the fortune of an American surgeon, Dr. B. A. Watson, of Jersey City, to supplement these ideas by the published results of an elaborate series of experiments.

In the course of the work one hundred and forty-one dogs were experimented upon. The animals were uniformly dropped twenty-five feet, and were so hoppled in one hundred and thirty-five cases that the blow was delivered on the nates, while the spine formed a nearly perpendicular line to this point. In six other cases the blow was received along the spine, while the head of the animal was sufficiently raised to prevent its coming in contact with the floor. Immediately before each trial a full record was made of the animal's weight, age, sex, pulse, temperature, respiration, and of the condition of the pupils. These observations were carefully resumed the day after the trial. Full pathological examinations, in gross and microscopically, were made by Dr. Frank Ferguson.

We can but briefly allude to the well-analyzed results given by Dr. Watson. The injuries received by the animals "were frequently compound and nearly always complicated, while in degree of severity they differed widely, being in some instances quickly fatal and in other cases they were so slight as to be imperceptible either in the post mortem or microscopical examinations." The last record of vital conditions in the animals surviving the fall was made just before they were killed by chloroform. In 5 cases there were fractures of either the ribs or vertebræ; in 11 an incomplete rupture of the sacro-lumbar ligaments was found, but in every instance some pathological change had resulted also in the cerebro-spinal axis. Quickly fatal results happened in 4 cases. The spinal ligaments were stretched in 5.

Of injuries to the viscera the most frequent was hemorrhagic infarctions of the lungs, 36; then followed, in order, congestion of kidneys, 32; lacerations of liver, 15; ecchymosis of psoas muscles, 7; pneumonic hepatization, 5; hemorrhagic infarctions of liver, 4; and others of less frequent occurrence, including rupture of spleen, 1; of liver, 1; of kidneys, 2; of pelvic blood-vessels with considerable hemorrhage, 2; and of bladder, 1.

Dr. Watson intelligently discusses many of the problems which this series of experiments presents. We deem his conclusions of sufficient importance to present them in outline as follows:

1. Concussive accidents never produce pathological changes in the cord unless great force has been applied to the spine. These cases are generally complicated with vertebral fracture or dislocation, rupture or stretching of vertebral ligaments, or distant injuries so severe as to quickly prove fatal.

2. The symptoms develop immediately and are rarely intensified by morbid changes in the cord; exceptions, fractures, dislocations, and slowly developing hemorrhage causing pressure on the cord.

3. It is very difficult to demonstrate stretching of vertebral ligaments on living subjects. The lesion is frequently overlooked on autopsy.

4. Injuries of the cord, with visceral injuries in addition, develop symptoms dependent on the existing complication. The termination of the case rests on the character of the traumatism.

5. Concussive force, though remotely applied, frequently results in the production of severe and even fatal traumatisms in various organs within the three trunk cavities.

News of the Week.

New York State Medical Association.—The seventh annual meeting of the New York State Medical Association, which will be held October 22d, 23d, and 24th, at the Mott Memorial Hall, 64 Madison Avenue, New York, will be an unusually interesting and profitable one. Almost every subject in practical medicine will receive attention. Over fifty papers are promised, besides general discussions on the management of labor, and on cerebral lesions with reference to operative procedure. Members of the profession in this city and vicinity are invited.

It is Reported that the United States Marine Hospital Service will recommend the plan of having a systematic examination of all persons intending to immigrate to this country. This examination would be made by physicians attached to the United States consulates. It is to be hoped that some such measure may be attempted. It is cheaper to keep out the sick, criminal, and defective classes, including anarchists, than to support them here or send them back.

Sanitary Supervision of Lying-in Hospitals.—At a convention of delegates from the various societies in the State for the prevention of cruelty, held at Albany, October 1st, a resolution was adopted recommending that all lying-in asylums, and all institutions for the care of children, should be licensed and under the inspection of local health boards.

The Secretary of the International Congress, Dr. Lassar, seems to have had a most unfortunate termination of his labors in organizing the Berlin meeting. It is stated that he left Berlin precipitately to escape the consequences of his rudeness while conducting the Empress through the exhibition; also, that his official statements at the last meeting of the Congress were incorrect. He is now reported to be insane; and this last supposition is, unfortunately, a probable one. Dr. Lassar did undoubtedly the most work and the best work of anyone connected with the organization of the Congress. He was a successful and popular man, and he now deserves the greatest sympathy from his professional brethren.

Prizes for Essays on Vivisection.—The American Humane Society offers two prizes, each of $250, for the best essays on the question whether vivisection should be permitted in the interests of humanity, and, if so, with what restrictions. Essays should be sent to George T. Angell, No. 19 Milk Street, Boston, before January 1st.

The Classical College and Medical Education.—We learn that Columbia College has voted to allow students to come up for the degree of A.B. at the end of the third year, thus shortening the time of preliminary education before professional studies are begun. Harvard has voted against the three years' course; but has at the same time voted "that a Senior intending to enter the Medical School and to take the full four years' course therein, may, under proper supervision, include in the requirements for the degree of Bachelor of Arts the courses on physiology and anatomy required in the first year of the Medical School, each of said courses to count as one full elective course."

A Physician Charged with Extortion.—Serious, but it is to be hoped unfounded, charges have been made against a well-known physician of this city for excessive and extortionate charges in connection with the examination and commitment of an insane patient. The sum of $1,550 was paid, it is said, for services as medical counsel and commissioner.

Lysol, cresol, aristol, sanitol, iodol, salol, listerine, volterine, pyoctanin, creolin, are some of the few modestly recommended antiseptics of the present day. But while each of these is struggling for a first place, we are being told that antiseptics are not now needed in surgery, and that asepsis is enough. This is sad news for the "ols" and "ines."

Ipecacuanha sine Emetine.—Surgeon-Major G. A. Harris, of Simla, invented a process by which emetine is removed from the ipecacuanha root without abstracting or decomposing any of its other ingredients. The powdered root is thus deprived of its nauseating properties, without, it is believed, interfering with its curative virtues. The preparation is being tested in cases of dysentery in the Medical College Hospital, with, so far as the trial has gone, promising results.—*Indian Medical Journal.*

The Therapeutic Value of a Large Fee.—There is a pleasing candor in the following extract from an article on the treatment of spermatorrhœa, by Dr. E. Lanphear, *Kansas Medical Journal:* "The payment of a good fee, as of $50 or $100 in advance, assists very greatly in gaining the faithful adherence of the patient and in hastening a favorable termination. Then the first prescription may be given."

We are Sorry to Observe that the World's Fair matters are not moving altogether smoothly in Chicago. The *North American Practitioner* says: "The crowning display of idiocy on the part of the World's Fair directors has been the appointment of a Smelling Committee of three physicians, to inspect the various proposed sites. One is a gynecologist, another a professor of clinical medicine, while the last has some claims to be known as a hygienist." Why our esteemed contemporary should fret because the members of the sanitary committee are pursuing certain special lines of medical practice, we do not see. Most sanitarians are medical men, and there seems no good reason why they should not sometimes be specialists. We trust that the World's Fair is not going to stir up intestine strife among the doctors of the city of high-pressure vocalization.

Public Medical Library in Kalamazoo, Mich.—Dr. E. H. Van Deusen, formerly Superintendent of the Michigan Asylum for the Insane at Kalamazoo, but at present retired from active practice, has recently donated to the city of Kalamazoo the sum of $50,000 for the purpose of the erection of a public library building. There is but one condition fixed to the donation, and that is expressed in the following language, quoted from the doctor's letter to the Board of Education tendering the gift. "The sole condition we affix to the acceptance of this proposition is, that a commodious room, with a small office attached, located and arranged satisfactorily to us, shall be permanently set apart for the exclusive use of the Kalamazoo Academy of Medicine. This use, however, to be restricted to the meetings of the Academy, and for its literary and reading-room purposes only. The Kalamazoo Academy of Medicine is an incorporated institution, and when permanently located will rapidly increase its library. The costlier works and periodicals of very great value and service to physicians, but too expensive to be owned by individuals, will be added to its collection. As the entire public will participate in the advantages thus to be secured, it seems to us both proper and desirable that the Academy of Medicine be a co-occupant of the proposed public library."

Keokuk Medical College.—The opening exercises of this new medical college were held on September 25th. Many of the members of the faculty were connected with the College of Physicians and Surgeons of Keokuk until the close of last term, when they withdrew and founded the Keokuk Medical College.

For the Insane Hospital at Blockley.—The Committee on Charities and Correction of Philadelphia recently decided to recommend an appropriation of $75,000 additional for erecting buildings on the Almhouse property for the accommodation of the insane; $150,000 had been previously appropriated for this purpose, but it was found that $75,000 additional were needed.

Dr. Ellwood M. Corson has received from Governor Beaver the appointment of Trustee of the Norristown (Pa) Hospital for the Insane, to succeed Charles Hunsicker, Esq., whose term has expired.

A Physician Complains.—Dr. George Price, of Altoona, Pa., complains of having been fined five dollars and costs by Mayor Burchfield, of that town, for failing to report a case of "contagious" typhoid fever. Dr. Price claims that he was not allowed in his defence to state that he had twice applied in vain to the Board of Health for proper blanks, nor to explain the "contagious" part of the charge.

A Congress of Hydrology will be held at Naples toward the end of October, under the presidency of Dr. C. S. Vinaj.

Influenza of a very malignant type is extensively prevalent in Japan. In Tokio alone 100,000 cases are said to have occurred.

Leprosy.—In China eight varieties of leprosy are recognized, and the disease is considered contagious, infectious, and hereditary, but is said to disappear in four generations. There are leper villages to which all suffering from the disease are sent.

The Contagion of Crime.—Dr. Lydston relates the following in the *Journal of the American Medical Association*, September 27, 1890: "Two school-boys were stealing apples together. They were detected and pursued. One was caught, while the other escaped. The one who was captured was sent to jail and thrown among criminals, from whom he acquired a moral contagion which infected his after-life. After his release those acts which before his incarceration were merely boyish pranks, assumed a criminal character, and he became a confirmed criminal. The boy who escaped remained in school, and doubtless kept up his mischievous tricks during his school days. He afterward studied law, became a lawyer, and eventually was elected a judge. Twenty-five years after the apple-stealing episode the judge sentenced his former comrade to death for murder." If crime is thus shown to be contagious, it will be in order to discover its specific microbe. Preventive inoculations with the attenuated virus of crime will then follow, and the human race will be purged of bad actions.

Mr. Edward Bellamy, Senior Surgeon to Charing Cross Hospital, has been accused of being the author of "Looking Backward," and has found it necessary to write as follows to the editor of *The Times:* "SIR—Will you kindly do me the favor of disclaiming the authorship of this popular work? Would that I were clever enough to have written it. I ask you to publish this letter, personally, to endeavor to put a stop to the correspondence (in all languages) enforced upon me from bearing the accomplished American's name. My reputed authorship is an eternal worry. Possibly an English surgeon, as I have the honor to be, might, with advantage to his pupils and publisher, write 'Looking Forward;' the result would be truly inspiriting to the intending practitioner of A.D. 2,000."

The Seney Hospital.—A strenuous effort is being made to raise sufficient money to complete the Seney Hospital, in Brooklyn.

Experiments Made on an Executed Criminal.—On the morning of September 1st a man was guillotined for having assassinated his mistress. Immediately after the execution the body of the culprit was removed to a dissecting-room, where Drs. Gley, Barbi, Couturier, and two military surgeons performed some very curious experiments, which may be found interesting. The beats of the heart were observed by Dr. Gley during more than six minutes, and some experiments were performed to demonstrate the independence of the ventricular and auricular contractions. It is asserted that this is the first time that such observations have been made on man. Dr. Gley then undertook a long research relative to the acidity of the different parts of the intestinal tract.

A Health Board on Chewing Gum.—The following bit of useful information is published in the monthly Bulletin of a certain State Board of Health: "Chewing Gum a Healthful Exercise.—We have seen the most excitable young lady, with a highly strung nervous organization, under its magic influence become as quiet and contented as the well-fed cow that lies in the barnyard chewing its cud. We know of nothing that will, with anything like such undiminishibility (*sic*) endure so much mastication. We have chewed a piece of this gum contentedly for two hours without any perceptible change in its bulk, and after remaining under the seat of the chair, on the under side of the table, or on the bedpost over night, if not found and confiscated, it was ready for as grand service as when first pressed between the molars. We believe that every ship sailing upon the high seas should be well supplied with chewing gum; and in time of danger of shipwreck the passengers should be furnished with at least a half-dozen pieces, so that if cast upon some barren and uninhabitable coast or island, they might have something with which to beguile the weary hours; and we know of nothing so innocently beguiling."—*The Boston Medical and Surgical Journal.*

Home for the Insane.—The report of Dr. W. W. Godding, the Superintendent of the Government Insane Asylum, Washington, D. C., has been submitted to the Secretary of the Interior. The number of inmates at the beginning of the fiscal year was 1,397, and at the close of the year 1,505, an increase of 108. They are divided as follows: Males, 1,155; females, 350. Of those admitted 115 were from the homes for disabled soldiers. The Toner Building has been opened for a distinct hospital for the sick, with nurses, and provided with all modern appliances. The Infirmary Annex Building is under contract, and it is expected that it will be completed during the present fiscal year.

Fidgets.—We are in receipt of the following interesting and valuable communication: "If you know of anyone who has got the fidgets right bad, tell them to suspend a flat-iron, or anything else the looks of which will not cause the fidget, from the ceiling of the room to near the floor, or the distance which causes the most agreeable sensation, set the weight to swinging a little, and sit down by it with the eyes fixed on it. If your patient is one of the sympathetic kind it will be likely to make her quiet. "If the weight is suspended from two hooks a little apart, it will have a better effect.—M. B."

Society Reports.

AMERICAN DERMATOLOGICAL ASSOCIATION

Fourteenth Annual Meeting, held at Richfield Springs, New York, September 2, 3, and 4, 1890.

PRINCE A. MORROW, M.D., OF NEW YORK, PRESIDENT.

The President's Address.—THE PRESIDENT called the meeting for scientific purposes at 10.30 A.M., Tuesday, September 2d, and proceeded to read his address, which gave a view of the present position of dermatology. Those engaged in this specialty had abundant cause for congratulation. Only a few years ago dermatology had little standing in this country. Previous to 1876 only twelve schools gave special instruction in dermatology. To-day, as he had learned by circular letter sent to a hundred colleges, it was recognized in the teaching faculty in eighty-six schools, probably in more. He asked, however, whether this showed a healthy growth or merely a mushroom growth. There was reason to believe that there were many and grave defects in the existing system of instruction. It is not the quantity but the quality and efficiency of the instruction which constitutes the criterion of its value. For successful teaching of the treatment of diseases of the skin two conditions are essential, namely, capacity in the instructor, and abundance and variety of clinical material. It must be admitted that the capacity of some of the teachers in our medical schools is doubtful, while the clinical material in the majority of cases is inadequate. Even in large cities the clinical material is too much dispersed. In New York, for instance, instead of having a central hospital for all dermatological cases as they have in Paris, this clinical material is dispersed in various dispensaries and hospitals in the city. For a thorough study of cases and of the results of treatment, a hospital is necessary. In medical schools cases of skin disease should be presented only to advanced students; not to those taking the first and second year's course. The study of these diseases should be obligatory, which is not now so in any school in this country, as far as he knows. If clinical material were not abundant, and the study of dermatology made obligatory, he thought it a question whether it would not be better to leave instruction in this department to post-graduate schools. It was a question also whether this post graduate instruction could not be better provided for in organized institutions than in independent organizations.

Nomenclature.—New names were being introduced into dermatology which were not destined to retain a permanent position, and while an essentially new disease required a new name, yet he offered a protest against the present neological craze. He suggested the propriety of introducing some subject for special discussion at the annual meetings.

Observations on Prurigo, Clinical and Pathological.—Dr. R. W. TAYLOR, of New York, read the paper. At the first meeting of the society Dr. Campbell read a paper on prurigo, and it appeared that only six cases had occurred in the experience of those present. New interest had been excited since the reading of Zeisler's paper on this subject last year, in which he gave accounts of twelve cases seen by him in Chicago. The combined experience of all present at that discussion included only eighteen cases. Dr. Taylor thought the disease more common in America than these statements would lead one to suppose. It was probable many cases escaped recognition and were classed as eczema, scabies pedicularis, ecthyma, impetigo, and even ichthyosis. This was due in part to the fact that there were no good plates representing the clinical aspects of the disease accessible to the general profession. He undertook to remedy this deficiency to some extent by giving photographs and a full description of a recent typical case, and also alluded to the casual concomitants and modifying conditions during the course of the disease. The patient was a healthy girl, aged nine, of healthy American parents, in good circumstances, healthful surroundings. When four years old she began to scratch, and the appearance of little red pimples on face, forearms, and legs led the parents to think they were due to mosquito bites. The disease had recurred every year up to the child's visit to the hospital in January of this year. The expression of the face was rather dull, the color of the typical white, somewhat ashy, hue of prurigo. Over the forehead, temporal region, and cheek was a copious eruption of small conical papules, some whiter than the skin, others of rather yellowish hue, and others capped with a blood-crust, the result of scratching. They were not developed on the site of sebaceous glands. There was no marked dryness or want of vitality in the hair as he had seen in severe cases; there was slight mealy desquamation in the scalp. As pointed out by Hebra, the eruption did not appear on the neck and nucha, but began to develop where the shoulder merged into the neck. The principal eruption was on the back of the hand and forearm and on the outer and anterior surface of the legs, where the papules were as large as a split pea; some on the arm, buttocks, and thighs. They were scattered without semblance of grouping, conical in shape, firm, some of the color of the skin, others of reddish hue, others capped with a blood-crust. Variations in the appearance of the disease were observed under certain complications, and shown in photographs. Sections had been studied under the microscope by Dr. Ira Van Giesen.

A Clinical Study of Pruritus Hemialis—Winter Itch, Frost Itch, etc.—DR. W. T. CORLETT, of Cleveland, read the paper. The affection under consideration was first pointed out as a disease *sui generis* by Dr. Duhring, and about the same time by Jonathan Hutchinson, since when it had been little written about. It is seldom seen save in certain localities; is seen in the Southern States only during cold waves, is seldom encountered in the clinics at London. On the southern border of Lake Erie, the writer's home being Cleveland, he could say the disease was well defined and not uncommon. He related three cases illustrating different points of interest connected with the disease. In one it had recurred during the frost season for over twenty-two years; in another the eruption had the appearance at times of urticarious patches, two or three inches in diameter, confined to the extremities, subsiding in about ten minutes, leaving for a while a dark yellowish spot. The third case was in a negro, showing that that race was not exempt. The writer's experience went to show that the state of the general health had no appreciable effect on the pruritus; that the local irritation of the clothing, although capable of aggravating the malady, was not of itself able to produce it; meteorological conditions appeared to be the main etiological factor. These were most potent with a low temperature, low humidity, and a wind blowing from the northwest. These influences were favorable to evaporation, and the low temperature reduced the glandular activity of the skin to the minimum. As a consequence the skin became harsh, the peripheral nerves were irritated and the disease was induced. He did not think the primary irritation could be central, else in time it would give rise to a less fleeting disease. It was not infrequently associated with other neuroses of the skin, these neuroses having, however, no influence save probably in showing the peculiar susceptibility of the nervous system.

The treatment was largely palliative. Change of climate was best, if possible. Internal medication seemed to have little effect. Locally he had used with advantage ichthyol and resorcin. Choose a warm and moist climate.

A Study on Pruritus.—DR. E. B. BRONSON, of New York, read a paper on "The Sensation of Itching" (see p. 425). He thought he was warranted in drawing the following conclusions: 1. That there is a sense of contact independent of the sense of pselaphesia. 2. That this sense of contact is the sense disturbed in pru-

ritus. 3. That it concerns primarily simple cutaneous nerves, or nerve-endings situated superficially and probably in the epidermis. 4. That the disturbance in pruritus is of the nature of a dysæsthesia due to accumulated or obstructed nerve excitation, with imperfect conduction of the generated force into correlated forms of nerve energy. 5. That scratching relieves itching by directing the excitation into freer channels of sensation, sometimes, especially when severe, substituting for the pruritus either painful or voluptuous sensations. 6. That the voluptuous sensations which may attend pruritus are a manifestation of a generalized aphrodisiac sense, representing a phase of common sensation that has its source in the sense of contact.

Cases of Cutaneous Tuberculosis, with Histological Studies.—Dr. J. T. Bowen, of Boston, read a paper containing the histories of a number of cases of cutaneous tuberculosis, together with histological studies, and expressed the view, also entertained by Dr. White, through whose courtesy some of the cases were seen, that several affections of the skin not yet recognized as inoculable would be proven to be so, and their relation to tuberculosis be demonstrated.

Remarks on the Treatment of Dermatitis Herpetiformis.—Dr. L. A. Duhring, of Philadelphia, said that the several papers published by him on dermatitis herpetiformis during the past five years had contained no reference to treatment. Having reported ten or twelve cases, it seemed appropriate to now speak of this exceedingly rebellious disease. Each group of cases based on the etiological factors at work required special handling. A speedy cure was not to be looked for. It must be remembered that the disease, as a rule, was multiform in character, and the several varieties naturally called for different formulæ, especially as to the strength of the remedy. His experience had been that milder remedies were called for in the erythematous than in the vesicular and bullous forms. A difficulty to contend with was the tendency of the disease to repeat itself, a new crop coming out before the older disappeared. Almost all his cases had been chronic, and previously undergone all manner of treatment. He had long since arrived at the conclusion that most benefit was to be derived from stimulating applications, especially those which acted as revulsives—tar, carbolic acid, sulphur, thymol, ichthyol, resorcin, etc. That which had proved of greatest value in his hands had been sulphur ointment, two drachms to the ounce, applied by thorough and long rubbing, so as to make a positive impression upon the skin, causing, as it were, local shock. Special emphasis was placed upon the manner of making the application. Internal remedies had proved of little avail in most cases.

A Case of Atrophia Maculosa et Striata following Typhoid Fever.—Dr. F. J. Shepherd, of Montreal, presented the history of the case, illustrated by photographs. It occurred in a boy, aged fifteen, who was brought to the hospital with typhoid fever. During the course of the disease he was delirious, and had epileptic attacks, macular lines formed, extending across the patellæ and around the anterior aspect of the thigh as high up as about the middle, some being several inches long. They were of reddish color, became paler, not distinctly shiny, and were grooved. The boy left the hospital without his knowledge. The interesting point in the case was the occurrence of the atrophic lines in a boy during acute fever. He did not think their presence could be accounted for, as they were in œdematous subjects, by stretching. There seemed to be a nerve element in the causation.

Immigrant Dermatoses.—Dr. J. C. White, of Boston, read a paper with this title. It included an account of the affections of the skin induced, 1, by life on shipboard; 2, those induced after arrival by conditions not existing previously; 3, diseases of the skin seen in other countries, but not in native Americans.

Conditions on shipboard tending to induce skin affections were mental depression on leaving home, seasickness, filth and foul air, constipation, inability to take exercise, contact with others having contagious disease. It was not uncommon for young persons to come a week or ten days after landing with an urticarial, bullous, or eczematous eruption. Vaccination on shipboard not infrequently left a local sore of wider area than usual, due perhaps to depressed state of health and the fact that the patient had not been revaccinated since childhood. Under the second head the causes were new agencies not existing at home, among them being, perhaps, mosquitoes. Under the third head, imported affections, the most common was scabies. Among others was that rare affection, melanosis lenticularis progressiva, none of the cases here, as far as he knew, being in native American stock. Prurigo might also be regarded as an imported disease, and was seen scarcely elsewhere than in cities with a large foreign population, like New York and Chicago.

The relative prevalence of vegetable parasitic affections among us was likely to be largely influenced by immigration. Tinea favosa, tinea trichophytina, tinea versicolor, were more common in countries from where we receive many immigrants than they are here. The same is true of tubercular affections of the skin, and he was disposed to regard lupus, scrofuloderma, scrofulous gummata, tuberculosis verrucosa, etc., as closely allied affections, inoculable and auto-inoculable. Leprosy was another imported disease, coming from many sources.

In conclusion the author suggested the propriety of memorializing the national Government with regard to carrying out the following measures: 1, To cleanse all immigrants of animal parasites on landing, by treatment of person and clothing; 2, to retain in quarantine all immigrants with other contagious diseases, including venereal affections, a sufficient time for treatment; 3, return to their homes all persons affected with such contagious diseases as it is impracticable to treat in such manner, as leprosy, tuberculosis, and advanced syphilis; 4, to provide for efficient medical inspection at foreign ports of immigration with the power of arresting importation of dangerous diseases to this country.

A Case of Second Infection with Syphilis, and a Case of Syphilitic Infection in a Person Hereditarily Syphilitic.—Dr. R. W. Taylor, of New York, gave detailed histories of the two cases, which had come under his observation within a year. The first was in a sickly looking woman, aged thirty-eight, who entered Charity Hospital in January last. Eleven years ago she had syphilis, having had hard swelling of the external genitals, enlargement of the glands, eruption shortly afterward all over the body, headache at night. The second year she had rheumatoid pains, mucous patches; the third year serpiginous syphilides, etc. She married and gave birth to two weakly children which soon died. Her husband dying, she again lapsed in virtue, and turned up in Charity Hospital in January last, broken down in health. There were typical miliary syphilides scattered over nearly the entire surface. All the gangha were markedly enlarged. There were mucous patches of the tongue and mouth, and evidences of alopecia. She suffered pain in the joints, worst at night. The second attack was much more severe than the first. She was improving under mercurial treatment.

The second case was one of acquired syphilis in a person hereditarily syphilitic. The woman came to him first in 1879, aged nineteen, when he treated her for destructive syphilitic sore on the face, arising from hereditary syphilis, a clear history of which was afterward given him by her mother, who acquired syphilis three months before the child's birth. The child had a rash, condylomata cuta, sniffles, was weakly, etc. Five years after his patient's first visit, 1885, she returned, and had then macula roseola and scaling syphilides all over the body; condylomata of the genitals, mucous patches of the pharynx, etc. The infection began in the right labium, and was contracted from the husband. The glands were all en-

larged; there was alopecia. She had since been cured. The author reviewed and criticised published cases, which were few.

Electrolysis in the Treatment of Lupus Vulgaris.—Dr. G. T. Jackson, of New York, in a paper on this subject said the advantages which electrolysis offered in the treatment of lupus vulgaris, compared with other and older ones, were as follows: 1. It is comparatively painless, and there is no need of putting the patient under an anæsthetic. 2. There is not the slightest loss of blood, and thus there is no dread of a surgical operation. 3. The patient is not kept a moment from his regular business, there is no deformity caused by the treatment, there is no after-treatment or application to mar the appearance. He is also spared the discomfort of a swollen face and eyes, the ordinary attendant on the arsenical or pyrogallic-acid treatment. 4. The treatment goes to the root of the disease, to the bottom of the tubercle, with far more exactness and less damage to the surrounding skin than any other caustic or surgical method. 5. The scar left is smooth and not unsightly. 6. The result obtained is as good as, if not better than, that by any previous method. He felt sure the members would have cause to be pleased with the method should they give it a trial.

Plica.—Dr. H. W. Stelwagon, of Philadelphia, showed photographs of a case which he saw a few months ago. He was not sure that plica was the right name for it. The woman, Irish, came to be treated for acne, and called his attention to a lock of hair, as thick as one's thumb, springing from the middle of the occipital region, closely matted together, and falling as low as the ankles, terminating in a brush-like end. It was not sticky, had begun to grow four years before, had no apparent cause. The rest of the hair fell over the shoulders and was not matted. There was absence of filth.

The Treatment of Erysipelas.—Dr. C. W. Allen, of New York, based this paper on the results of treatment during the past two years of 419 cases in the hospitals on Blackwell's Island, not under his care, and 47 cases in his own practice during the same time. Of the former, 21 died; average stay, twenty-two days; facial erysipelas in 267. Of his own 47 cases 24 were facial; deaths, 4; average stay, over seven days. The treatment employed was various, but was principally local, consisting in applications of different kinds. Dr. Allen thought that, although tending to pursue a definite and usually favorable course, the disease could be checked in its course by treatment. Among the applications were boracic acid, iodine, resorcin, bicarbonate of sodium, ichthyol, collodion, aristol, scarification with the knife, and plaster strips encircling the limb. He was disposed to think favorably of scarification and adhesive plaster, separately or combined in the same case, but had tried them in only about two cases.

Notes on Pilocarpine in Dermatology.—Dr. H. G. Klotz, of New York, in this paper first gave a review of the history of pilocarpine in dermatology, and said it had not met with the acceptance which one might have supposed if its therapeutic virtues had been at all proportionate to its diaphoretic qualities. The author had employed this remedy in a few cases, including some of eczema, pruritus of the anus, and affections with dryness and irritation. The result had been such as to encourage him to give it a further trial. It might be given internally, or by hypodermic injection—small doses, long continued. A tenth of a grain was likely to prove sufficient to keep the skin moist.

Aristol.—Dr. C. W. Allen, of New York, read a paper giving the results of his experience with this new remedy, and summed up with the statement that it seemed to possess valuable cicatrizing, granulating, and stimulating qualities, was void of the objectionable odor of iodoform, and seemed valuable in certain dermatological cases.

Results of Treatment of Dermatological cases by Sulphur-water at Richfield Springs.—Dr. C. C. Ransom, physician in charge of the new bathing establishment, by invitation gave the results of treatment of dermatological cases there. Since the new bath had been completed during the summer twenty-two cases had been treated, including nine of eczema, one of psoriasis, four of seborrhœa, one of pruritus, two of urticaria, etc. There was marked improvement in nearly all of these cases, and in some a cure. The baths were of a temperature usually from 95° to 106° F., lasting from seven to fifteen minutes. A longer stay in the sulphur bath had a depressing effect lasting some hours.

The Association adopted resolutions, expressing appreciation of the very extensive and complete equipment for water treatment established by Mr. Proctor at the Springs.

Among those taking part in the discussions on the papers besides the readers named were Drs. Hardaway, of St. Louis, J. E. Graham, of Toronto, and James S. Howe, of Boston.

Officers Elected.—*President*, Dr. F. B. Greenough, of Boston; *Vice-President*, Dr. L. N. Denslow, of St. Paul; *Secretary and Treasurer*, Dr. G. T. Jackson, of New York.

THE MEDICAL SOCIETY OF VIRGINIA.

Twenty-First Annual Session, held at Rockbridge Alum Springs, Va., September 2, 3, and 4, 1890.

About one hundred and fifty members were present during the session. The membership of the Society is about eight hundred. The annual addition (as it was this year) to the membership is about fifty, exclusive of the losses by death, etc.

After prayer by Rev. Dr. Garrison, of Philadelphia, Pa., and the "Address of Welcome" by the resident physician and an honorary fellow of the Society, Dr. J. Edgar Chancellor, of the University of Virginia, Dr. John S Apperson, of Marion, Va., delivered "The Address to the Public and Profession."

The committee appointed to examine the several essays offered in competition for the Dr. Hunter McGuire prize of one hundred dollars for the best original essay on the "Diagnosis, Pathology, and Treatment of Chronic Cystitis in the Male," reported that the prize had been awarded for the essay signed "*Causa Cessante, Cessat Effectus.*" On opening the sealed envelope of the letter, the author was found to be Dr. R. M. Slaughter, of the Theological Seminary, Va. As soon as the award of the prize was made, the announcement was authoritatively made that Dr. Hunter McGuire would offer another one-hundred-dollar prize, to be awarded next year to the practitioner in Virginia, West Virginia, or North Carolina, who would write the best essay on a subject to be hereafter announced through the office of the Secretary of the Society.

During Wednesday morning session the President, Dr. Oscar Wiley, of Salem, Va., delivered "The Address of the President," which was mostly of local or Virginia interest. Immediately succeeding this address the subject for general discussion, "Summer Diarrhœa of Children," was called, and lasted over into the night session, thus indicating the degree of interest manifested in the subject. But while every paper and every speech confirmed an old truth, and was well listened to, nothing seems to have been developed by the discussion which is not now common property of the profession.

Election of Officers.—During the afternoon session the following officers for the ensuing year were elected: *President*—Dr. William W. Parker, of Richmond, Va.; *Vice-Presidents*—Drs. J. W. Dillard, of Lynchburg, Jacob Michaux, of Richmond, and H. M. Patterson, of Staunton; *Recording Secretary*—Dr. Landon B. Edwards, of Richmond, Va.; *Corresponding Secretary*—Dr. J. F. Winn, of Richmond, Va.; *Treasurer*—Dr. Richard T. Styll, of Hollins, Va.; *Chairman of Executive Committee*—Dr. Hunter McGuire, of Richmond, Va.; Dr. Charles M. Blackford, of Lynchburg, Va., to deliver "The Address to the Public and Profession" during session of 1891, to be held in Lynchburg, Va., some time during month of

October. Subject for general discussion during session of 1891, "Acute Dysentery;" Leader, Dr. P. B. Green, of Wytheville, Va. To fill vacancy on Medical Examining Board of Virginia, from the Norfolk Congressional District, Dr. Alfred C. Palmer, of Norfolk, Va.

Advances in Ophthalmology.—Dr. Robert L. Randolph, of Baltimore, Md., Chairman of the Section, reviewed two articles, one by Professor Graefe, of Halle, the other by Steffan, of Frankfort, on antisepsis in the operation for cataract. The reviewer inclines to the arguments of Graefe, who upholds the value of antisepsis, in opposition to Steffan, who regards the method as useless. Dr. Randolph spoke of the new treatment of detached retina by the injection of tincture of iodine. He emphasized the value of fluorescein as a means of diagnosing lesions of the cornea, and mentioned some experiments of his own and of Kalinski in connection with the production of cataract in the lower animals by feeding them on naphthalin.

Advances in Laryngology and Otology.—Dr William F. Mercer, of Richmond, called attention, 1, to the conclusions of Semon in his investigation in regard to the transformation of benign growths of the larynx in consequence of intralaryngeal operations. 2. The early treatment of naso-pharyngeal and throat affections in young growing children as a cure or prevention of certain derangements of the nervous system and impairment of the intellectual power existing or shown later in life. 3. Nasal intubation as an easy and ready mode of cure in hypertrophy of the soft intranasal tissues, deviations of the cartilaginous septum, fractures, etc. 4. The easy and certain means or diagnosis of empyema of the antrum of Highmore by the illumination of the maxillary bones by an electric lamp introduced into the mouth, and the importance of perfectly free drainage.

In the branch of otology he calls special attention to the great importance of the early recognition of, and treatment for, acute suppurative otitis media following scarlatina, thereby greatly reducing the high percentage of deaf-mutism from this cause.

Dr. Joseph A. White, of Richmond, Va., read an excellent paper on "The Importance of Nasal Surgery and Nasal Therapeutics in the Treatment of Aural Catarrh;" and he presented another paper on the "Relations of Refractive Errors and Muscular Defects in Asthenopia, Ocular Headaches, etc."

Operation for Cataract and Strabismus in Children.—Dr. Charles M. Shields, of Richmond, presented a paper on this subject. As to the best time for operation for cataract in children the text-books have little to say, and as a large proportion of the cases were zonular and allowed some vision, the operation was generally put off until better vision was needed for educational purposes—ten to thirteen years. At this age the retina has often lost its functional activity from disuse, and the results of the operation are unsatisfactory. His last five cases were cited in support of the argument for early operation. Three of them were between the ages of ten and thirteen, and although the operation itself was successful and a clear pupil obtained, the visual results were not satisfactory. The other two cases were much younger—one three years the other six months. Both were needled and gave the most satisfactory results. Dr. Shields thought the earlier the operation for cataract in children the better the results, for the following reasons: First, In the young the eye is more tolerant of surgical procedures; second, the child is given the advantages in gaining education that vision secures; and thirdly, the permanent visual results are better than would be obtained at a later age.

As to the age for operation in strabismus, Dr. Shields thought that usually suggested (six or seven years) early enough in alternating squint, as vision in either eye does not suffer from delay, both eyes being alternately used; but where strabismus is confined to one eye, the monolateral form, the earlier the patient is operated on the better.

In this form of squint vision is constantly suppressed in one eye and amblyopia from disuse results, making the eye useless. The operation should be performed in the monolateral variety as early as it is recognized.

Treatment of Strabismus.—Dr. Alexander Duane, of Norfolk, furnished a paper on the "Modern Treatment of Strabismus." In it he contrasted the superiority of the modern precise tests and of modern technique over the old hap-hazard way of operating, and urged the necessity of making the tests both with prisms and by the parallax and excursion movements during and after the operation, and of limiting or redressing the latter, according to the results thus obtained. After a brief sketch of the varieties of squint, in which he followed very closely Mauthner's classification, he went on to the question of operative treatment. In concomitant strabismus he strongly separated the cases with relaxation of the tendons, which demanded advancement, from cases with excess of tension, requiring tenotomy. A remarkable instance of the first class was given, which was markedly benefited by advancement even when that operation seemed on *a priori* grounds to be calculated to increase the deformity. In paralytic squint tenotomy of the associated antagonist, according to Alfred v. Graefe's rule, was recommended wherever practicable; but in paresis of the superior and inferior rectus advancement of the paretic muscle was indicated. In three hundred and fifty eye cases, the author had seen two of paresis of the superior oblique, one of which was markedly improved by operation.

Otitis Furunculosa.—Dr. John Herbert Claiborne, Jr., of New York, presented a communication entitled "Otitis Furunculosa" (Boils in the Ear).

He summed up his conclusions in the following way: 1. Furunculosis of the outer ear is a local disease. 2. The cause is the transmission by rough means, beneath the skin, of pyogenic microbes. 3. The prognosis is good, both as to the life and hearing of the individual. 4. The treatment consists in local antisepsis (solutions of boric acid, carbolic acid, etc.), moist heat, and incision of the furuncles when they point.

Catarrhal Otitis Media.—Dr. Laurence Turnbull, of Philadelphia, Pa., read by invitation a paper on "Aural Catarrh," which treated mostly of the results of the disease. He says, in passing, that most of the so-called hearing restorers act most injuriously upon the sensitive ear, and are of no benefit except to those having a hole or perforation of the drum-membrane, or to those who suffer relaxation of the small bones of the ear, which become sometimes separated from the membrana tympani. In many instances they have acted as a foreign body; and when they have a metal stem, as is often the case, they are sure to set up a "running ear." The only form of artificial covering to the diseased perforation of the drum-membrane should be a delicate gauze or rubber, charged with an antiseptic solution, to protect the ear from the floating microbes in the air, and from temperature changes. He then detailed at length a correspondence with a patient who had tried to use some of the artificial aids referred to. In addition to the measures recommended in his book for such a case, he advised massage to the ears, and valerianate of strychnia for the nervous debility of the patient; and as to hygienic rules, he advised a life in an elevated region, dry house, woollen underwear, and the use of a small piece of wool in the ears when out driving, etc. Do not let water get into the ears.

Lifting the Epiglottis.—Dr. C. M. Blackford, of Lynchburg, presented a paper describing "A New Method of Lifting the Epiglottis, devised by Dr. Samuel P. Preston, of Lynchburg." The instrument used consists of an ordinary laryngeal silver probe, with the last half-inch bent so as to make a right angle with the remainder. Rings are soldered on the shaft of the probe, through which the third and fourth fingers of the left hand are passed. Introduce the probe, and let the bent portion press down on the glosso-epiglottidean ligaments. This pressure

tightens the ligaments and thus lifts the epiglottis. This instrument is used in the Throat Clinic in Vienna. By holding the laryngeal mirror with the thumb and forefinger of the left hand, with this elevator between the third and fourth fingers of the same hand, the right hand is left free for use. The pressure of the probe is not great enough to cause retching, and does not cause special inconvenience to the patient.

Palpo-traction.—Dr. Alfred C. Palmer, of Norfolk, read a paper in which he described a new form of treatment which he had been using upon the lids of infants, which he termed "palpo-traction." It consisted in manipulating the lids of the new-born, while the tissues are in a pliable state, for the correction of tendencies to entropion, ptosis, etc. He reported a case in which the lower lid of infant contained a fold of surplus skin that lay along the roots of the lashes, which sooner or later, in his opinion, would have caused them to become inverted upon the ball; but by creasing the skin lower down on the surface of the lid, and holding it for five minutes for some days in succession, he succeeded in establishing a fold in its proper place out of harm's way. He called the attention of obstetricians to the importance of making careful examination of formation of lids of the new-born.

Dr. L. H. Keller, of Luray, read the "Report on Advances in Materia Medica, Therapeutics, etc.," in which he called attention to forty-three recently introduced drugs or preparations.

The Diagnosis of Pelvic Disease; or, When to Operate.—Dr. I. S. Stone, of Lincoln, read a brief paper in which he endeavored to show the chief points of diagnosis in the pelvic diseases of women, laying especial stress upon the indications for operative treatment. He claims that the profession is practically a unit upon the surgical treatment of pelvic and abdominal tumors, as well as extra-uterine pregnancy and pyosalpinx when recognized. The treatment of these conditions by electricity is not only barren of good results, but is hazardous in itself, and leaves the case still more difficult to deal with when operation is resorted to. The author regards salpingitis in rural districts as quite a common occurrence following puerperal cases, its symptoms so closely resembling pelvic peritonitis and cellulitis as to render diagnosis impossible. This salpingitis is the same as that seen in the cities, with the difference that gonorrhœa, being rare in the country, infection rarely occurs; consequently pyosalpinx is not so frequently seen. These cases of salpingitis frequently recover without leaving a trace of disease to be ascertained by vaginal examination. After urging positive views upon the treatment of these cases of pelvic disease, the writer thought it of far greater importance to decide not to delay operation than to try and name the disease after it was plainly one resisting ordinary treatment and necessitating exploratory section. The extent of the disease, the complications arising during operation, which are impossible of definition before, are the real dangers of the operation, and are often the positive obstacles to their successful treatment by any other than heroic measures.

Tubercular salpingitis also received attention, and the point was well taken that many cases of mysterious pelvic disease in young women are to be explained by properly investigating their cause. It was suggested that these cases are frequently aggravated after marriage, and that when no possible blame could be attached to the husband.

In response to invitation to open the discussion, Dr. George Tucker Harrison, of New York City, said that Dr. Stone had left but two points which he thought proper subjects of criticism. Dr. Stone seemed to look upon puerperal malarial fever as a disease of very minor importance. Dr. Fordyce Barker, some years ago, drew prominent attention to this subject. It is not a rare disease by any means in some localities. For instance, it is quite a common complication or sequel of labor in New York City. But it is not always easy to trace the development of the disease to the proper cause. It undoubtedly belongs to the puerperium. In a case recently under his care, delivery was conducted under the most perfect aseptic principles, and yet, about a week after labor, puerperal malarial fever set in, and lasted seven weeks. Incidentally, he remarked that rheumatism is a frequent sequel of puerperal malarial fever. As to removal of the uterine appendages, etc., lately the operation has become much abused. Novices, as well as specialists of high and low degree, are performing laparotomies with a recklessness that calls upon the profession to demand a halt. He cited an instance under his advice where laparotomy was advised by a specialist under the erroneous diagnosis of pelvic structural disease, instead of normal pregnancy, as the case proved to be. Of course laparotomies are demanded in certain selected cases, but he condemns the popular wholesale removal of ovaries, etc., and thinks their causeless removal should be rebuked as severely as was Baker Brown for his wholesale removal of clitorides years ago. It should not be forgotten that mental derangement, even, has followed the removal of the sexual organs of the female. It is a difficult matter to decide in most cases when to operate; and no one should undertake so radical an operation until after the exhaustion of every possible means of relief, unless, of course, the diagnosis of incurable structural disease of the ovaries or appendages is apparent. Extra-uterine pregnancy is about the most important subject that can claim the attention of the obstetrician, as well as the laparotomist. The condition is too often not recognized until too late to render service by surgical means. The diagnosis should be made early in order that the operation may save life. Tait is all wrong as to his pathology of extra-uterine pregnancy. He confounds hæmatocele and hæmatoma with extra-uterine pregnancy. Hæmatocele is an effusion of blood into the peritoneal cavity, about Douglas's cul-de-sac. Hæmatoma is an escape of blood into the folds of the broad ligament alone. But in extra-uterine pregnancy of the tubal variety, after the probable cessation of one or more menstrual periods, there is often an irregular hemorrhagic discharge per vaginam, which very generally precedes rupture of the tube by several days.

Dr. Joseph Price, of Philadelphia, Pa., wished to emphasize Dr. Harrison's remarks as to reckless and unnecessary laparotomies. The operation has been too much overdone. It should be done only for an objective disease, not for a subjective disease. More of this work has been done in New York than anywhere else, and there it has undoubtedly been often abused. Furthermore, many operations that ought to have been well done have been imperfectly done; and such operations bring discredit upon surgery. The mortality resulting from laparotomies for ovarian, tubal, or uterine diseases has now been reduced to about two per cent. The time has come when simply opening the abdominal cavity for surgical purposes should never result fatally. This is proven by the results thus far had from McGuire's suprapubic cystotomy.

Dr. Price then exhibited some drawings made by Dr. Coe which are very unfortunate. He draws a pus tube nine inches long. If pus in the tubes can be diagnosed, cut for it. In other portions of the body pus cavities would be opened by any surgeon. Why, then, not open a tube filled with pus? He pointed out a number of misleading points in Dr. Coe's plates and in his methods of operating. Extirpation of the ovaries, tubes, etc., should have for its object to save life. He has generally found that the country doctor was right in his diagnosis of the condition which required the laparotomy; hence he had but little to do other than to operate in cases of patients sent him from the country. He would advise that all forms of fibroids—even if not larger than a hen's egg—be extirpated. The results of operations for such removals have been most encouraging, and have made the mortality from such operations very small.

Another point Dr. Price wished to insist upon is to ex-

ercise the greatest possible degree of caution as to tampering with the uterus by intra-uterine medication and examinations, etc. Emmet says he has not passed a uterine sound for fifteen or twenty years. Treatment of the intra-uterine diseases should be conducted on the most conservative gynecological principles. Undoubtedly there are some intra-uterine diseases which should be treated locally; but he never dilates a cervix to enter the uterus—he is afraid to do so. And the reckless use of electrical treatment of uterine diseases has also produced many diseases which later required the skill of the surgeon. He has been called upon a hundred times to open the abdomen because of the after results of electrical treatment, and the same may be said of the results of operations for forcible rapid dilatation of the uterine neck. More prominent attention should be given to the the subject of gonorrhœa in innocent wives as the cause of many of their surgical diseases. The ravages of this disease in women are twice as great as by small-pox.

As to extra uterine pregnancy, Virginia has a right to be proud of her gifts to the army of obstetrical surgeons. Bingham, of that State, about a hundred years ago, did the first scientific operation for extra-uterine pregnancy. He also did the second scientific operation for extra-uterine pregnancy, nine years later. Dr. Price consumed the rest of his time in showing some plates, drawn by him from nature, illustrating ovarian and tubal pregnancies. In his large experience he has found rupture of the tube to occur almost invariably near one of the fimbriated extremities. As to simple ovarian abscesses, he has removed more of them than he has been able to find collected in all the books on the subject.

Dr. Hunter McGuire, of Richmond, remarked that Dr. Harrison said that Fordyce Barker was the first man to call attention to, and name, puerperal malarial fever. He asks to correct this. The late Dr. Otis F. Manson, of Richmond, was the first one to describe and designate this condition, and Dr. Barker had recognized this claim to priority. Dr. Price had said that the man who employed a sound or made intra uterine medications ought to have his head shaved. If for every one that he (Dr. McGuire) had made he had a strand of hair removed, he would be bald-headed. Dr. Battey is a great surgeon and a good man, and was the pioneer in important surgical work, but Battey's operation for normal ovariotomy would become obsolete. In Dr. McGuire's opinion it was a crime to take out normal ovaries for any nervous or hysterical condition. Some years ago he had done it, but he regretted it; it did no permanent good. When there was some pathological change in the ovaries or tubes, then, after failure by other means, the operation should be done, but all other means should be first exhausted. He himself had gotten much good in these cases out of galvanism. He did not agree with Dr. Price that all fibroids should be removed. In nine out of ten of the cases that came to him he advised the patient to let the tumor alone. If the growth was stationary, or nearly so, giving rise to no pain or mechanical obstructions, he would let it alone. If the gentleman knew how common fibroids were in the negro, and how many hundred negro women were working to day with fibroids of the uterus, in no way disabled for work by the tumor, he would not advise an operation in all cases.

Dr. Joseph Hoffman, of Philadelphia, Pa., said that until Emmet arose, only a few years ago, and protested against the hasty sewing-up of perineums and uterine cervices, etc., these operations were greatly abused. Battey's operation has proved a failure, and will be done away with. Others think that all forms of women's diseases are essentially cellulitis; but in ninety-nine cases out of one hundred this is a mistake. Tait has done nothing more than revive the pathology of forty years ago, and he evidently got it from Nonat, who fully discussed the subject as a peri-uterine and lateral phlegmon about 1846. Surgery ought to be resorted to only for the purpose of relieving pain or saving life. To puncture a pus-tube with the hope of curing it is idle, because tubal pus cavities are like the links of sausage. Hematocele is very rare; but Mr. Tait says when it does occur it is often mistaken for extra-uterine pregnancy. Exploratory incisions should be used only as guides for the surgeon to see whether or not he can cure a given case. Never cut down on an abdominal abscess or tumor and half finish the operation. Such half-finished operations injure surgery in professional esteem. Curetting the endometrium is bad practice. Under modern modes of procedure laparotomies are comparatively devoid of danger. Exercise common-sense in the selection of cases for operation. Don't think that because the operation is abused by some, it is totally unjustifiable in certain cases.

Dr. Edwin Ricketts, of Cincinnati, O., said that the field had been so well covered by the preceding speakers that he had nothing to add to the discussion. But the discussion of this very subject at this place reminded him that the immortalized McDowell was born in this county (Rockbridge). In 1809 he did his first ovariotomy. He then proceeded to give a brief history of McDowell and of the operation. It took years to establish the operation upon the plane of scientific recognition; but now the tendency in some sections is as much to abuse the operation as to resort to it solely for the promotion of the interests of the patient. Discredit comes upon the profession and upon surgery when the surgeon fails to make his diagnosis clear, and fails to return some degree of benefit as a compensation to the patient for submitting to so grave an operation.

Extra-uterine Pregnancy.—Dr. Isaiah H. White, of Richmond, spoke of the importance of early diagnosis and prompt treatment in cases of extra-uterine pregnancy. The physician's first intimation of such a condition, however, is when he responds to the hasty call to attend his patient in collapse, evidently due to peritoneal rupture. But if the patient rallies and gets well from the effects of the rupture, and if the fœtus becomes encapsulated, etc., the extra-uterine pregnancy may remain for years in a quiescent state—the fœtus, of course, being dead. In fact, he had attended a woman where the extra-uterine pregnancy had remained in a quiescent state for several years, and would probably have so remained for as many more, had not the woman become pregnant again. But the new pregnancy lighted up fresh peritoneal trouble—suppuration—and soon demanded his surgical attention for removal. He has either heard or known of many such cases. Some cases, indeed, of extra-uterine pregnancy are not known to exist until after death from other cause than the extra-uterine pregnancy. Such histories suggest that where extra uterine pregnancy may be reasonably suspected, and yet not proven, it may be well to court safety by passing a sufficient galvanic current through the mass supposed to be an extra-uterine pregnancy, to kill the fœtus, before the period for peritoneal rupture to take place, and then leave the developments for future consideration and action. The well-known laws of nature to accommodate itself to the gradually developed abnormal state of affairs may lead to the final delivery of the fœtus, bone by bone at a time, by self-protective ulcerations, through the rectum, etc. But when an operation is decided upon, what are known as the remnants of an extra-uterine conception are most probably altogether the products of the inflammatory action set up at the time of the passage of the fœtus through the rent in the tube into the peritoneal cavity. As to the strictured portions of pus tubes which have been referred to, and which give to the canal the appearance of rolled sausage, as seen at the butcher's stall, they are due to adhesive perimetric bands formed around the tube as the result of the pelvic inflammations. As to so-called "normal ovariotomy," Dr. McGuire is undoubtedly correct in deploring the results obtained, and in his determination never to undertake the operation again unless it is evident that there is structural disease of the ovaries. It is not too much to suppose that many survivors of the operation

itself regret that they are alive. Dr. White joined in the chorus with the other speakers in sounding the voice of extreme caution as to intra uterine examinations, medications, curetting, etc.

Operative Treatment of Reflex Neuroses.—Dr. Landon Carter Gray, of New York, in response to a call for remarks on the subjects under discussion, said that in this enlightened day he regarded the further resort to "Battey's operation" for the wholesale cure of nervous diseases of the female as a crime. Baker Brown, years ago, was properly expelled from fraternal relationship with the profession of his country because of the almost numberless useless clitorodectomies he performed. Some experience and publications of Dr. Lewis A. Sayre, only a few years ago, led the profession into the unnecessary practice of cutting off prepuces for the relief of certain nervous troubles. Stevens should have been commanded a halt in the cutting of eye muscles for the so-called cure of chorea and other nervous troubles which were not relieved thereby. All such procedures are proven to be failures when recommended or resorted to as surgical panaceas. In almost all the cases where such operations have been resorted to for the cure of nervous diseases, unless there were more distinct occasions for such mutilations, even when relief did seem to follow, it has been shown that such relief was only temporary; and even this result could be more satisfactorily accounted for on the known therapeutic laws of strong mental impression than upon the direct benefits of the several operations themselves. On this principle "normal ovariotomies" have undoubtedly for a while given apparent respite from attacks of hysteria, epilepsy, etc. But sooner or later, in all the cases that have come under Dr. Gray's observation, the attacks have returned and become severer, and the patients have become more piteously invalided by the very reason of their castration. As long ago as 1828 this principle of mental impression was put to scientific tests by Esquirol. He divided numbers of epileptics into groups. To one group he gave one class of remedies, with the adjuvant of strong mental impression as to the benefit to be derived from the so-called "new treatment"; to another group of cases he gave another class of medicines; and to another group another class of medicines still; and to another group he gave simple colored water, etc. Each group of cases did equally well for a time, but soon relapses began and all went back to their former states of severity. Up to the present time no remedy has stood the test of trial in doing permanent good in epileptic diseases except it be the bromides. Undoubtedly operations are more beneficial when performed upon the strongly impressionable class of patients; but even then it is best to select that form of operation which the patient herself believes will be best for her own relief. Simple incisions, as if the operation had been performed, and leaving the patient to come out from under the anæsthetic to persuade herself that the operation had been thoroughly performed, had done as much good as the real operation of normal ovariotomy.

Dr. William W. Parker, of Richmond, Va., was surprised that the publications of one or two distinguished men in the profession, who had probably seen the results of some reckless intra-uterine medication or rough examinations should drive practitioners to give up the valued lessons of their experience. Of course gentleness and judgment are required in resorting to intra-uterine examinations and medication. In a large practice since the war, he has almost daily made such examinations and treatment, and he is yet to hear or believe that any harm has resulted. On the contrary, he has thus diagnosed and cured numberless cases that no doubt would have been in the hands of "specialists" had he done otherwise. Intra-uterine injections are perfectly safe if the usually recommended precautions are faithfully observed.

Dr. Harrison, as a personal explanation, said that he was not so wholly opposed to "Battey's operation" as his remarks might have led some to believe. He had seen some serious cases of nervous troubles permanently relieved, if not cured, where the ovaries were only moderately diseased, so far as could be detected after their removal. But Dr. Battey's original error consisted in naming his operation "normal ovariotomy." He thinks Dr. Battey justly entitled to the thanks of woman, and to the praise of the profession for having pointed out an overlooked field for future and thorough gynecological study.

Dr. Stone, in closing the discussion, thought it proper to remark that Dr. Barker's puerperal malarial fever is often nothing but the evidence of the existence of pus in the Fallopian tubes. He would not, however, undertake to deny that there is a pure puerperal malarial fever, as Dr. Manson had described prior to Dr. Barker's mention of the subject. As to Battey's operation, he never did but one, and the result was unsatisfactory. Hence he stood simply as an interested listener of the remarks that have been made to-day by gynecic surgeons and practitioners of such large experience and extensive reputation whose dicta will go far to shaping or establishing subsequent professional opinion on the subject.

Vertigo.—Dr. Landon Carter Gray, of New York, read a paper on this subject. He said that an important generic distinction between vertigo of organic disease and that of a functional nature is that the former is attended by less irritability and apprehension on the part of the patient than the functional form. Kidney, heart, and organic liver troubles cause slight vertigo, lasting only a short time. In vertigo due to kidney disease the headache sometimes disposes to hebetude or coma, occasionally convulsions; there may be œdema also. In vertigo of organic liver disease there is usually some degree of hebetude, or jaundice, or dropsy. Vertigo due to brain lesions will prove pathognomonic. Thus cerebellar vertigo causes titubation, or one-sided staggering gait, or sudden semicircular whirling. According to Dana, temporal lobe lesions may produce like symptoms. Spinal lesions are not apt to cause more than slight vertigo; in locomotor ataxia dizziness may occur when the patient's eyes are closed. Middle-ear and labyrinthal diseases also cause vertigo.

But there is a chronic vertigo, varying from a sudden sensation of loss of equilibrium to dread of going about, often attended by symptoms of other nervous disturbance, such as tingling of extremities, fulness about head, usually felt most at the vertex, with slight aural ringing, mild insomnia, irritability, etc. It is most common in young and middle-aged adults, and is most frequent in Northern climates in the first warm months of the year. In severe cases, even going from a cold into an over warm room will induce an attack. Neurasthenia is common. Tongue is usually unaffected, but there is generally an excess of uric acid or oxalate of lime in the urine. Hence Murchison gave to this symptom-group the name lithæmia. But Dr. Gray said many cases do not present evidence of liver trouble; nor is there a standard by which to judge of an excess of uric acid in the system; and again, cholagogues often aggravate the vertigo as well as nervous symptoms. He said that generally this peculiar form of vertigo is due to some chronic and persistent error of digestion—either of the nitrogenized or starchy elements of food, or of both. Constipation without coated tongue or foul breath is common in this form of digestive disease. Predispositions to gout or rheumatism seem to cause such trouble; but the exciting causes of the vertigo are mental or physical overstrain, great anxiety, malaria, very sedentary life, etc.

Therapeutically, in those not having neurasthenia, he gives twenty drops of dilute nitro-muriatic acid, before meals, in a wine-glass of water, and also one drachm of fluid extract, or two grains of solid extract of cascara sagrada three times daily, reducing the dose if it causes more than two feculent stools a day. Interdict all red

meat diet. In about ten days the patient will feel better generally, but the vertigo will still be unaltered. Then stop the acid, and, instead, give the best pepsine and pancreatine—pepsine immediately after meals, and pancreatine an hour and a half later. After a time gradually return to meat diet, but only once a day. In neurasthenic cases, in addition to this treatment, require the patient to take absolute rest—even sometimes in bed for two or three weeks. It is better to err on the side of enforcing too much than too little rest in these cases. In so radically differing from others with reference to the treatment of this chronic form of vertigo, he has only to say that his experience has taught him to so differ.

Dr. William W. Parker agreed with Dr. Gray that the cause of the vertigo was mostly of a dyspeptic character, and hence a very rigid diet is the essential element of treatment.

Dr. Hunter McGuire said that after a great deal of study of cases of vertigo of the chronic kind, so well described by Dr. Gray, he had come to the conclusion that they were typical of a form of lithæmia, and that they originated in some derangement of the portal circulation. He had noticed that if the liver keeps on acting well—to use the common form of expression—the vertigo does not occur. Such inaction of the liver in these cases is not always manifested by the characteristic furred tongue, etc., for that may be red and moist, while the fecal discharges may show a grayish or putty look. But there is always evidence of some form of gastric or bowel fermentation. He has derived benefit from a somewhat continuous use of cholagogue purgatives, so as to get two or three feculent actions a day, and then by the prolonged use of minute doses of bichloride of mercury, short of ptyalism. He keeps it up in doses of from one-sixty-fourth to one-eighteenth of a grain, three times daily, for a period of a month or more. Then he gives a perfectly neutral solution of extempore prescription of the hypophosphites of lime and soda. He is afraid to depend upon any of the prepared sirups of the hypophosphites on the market in such cases.

Dr. Isaiah H. White is satisfied that the form of vertigo described is an expression of lithæmia, or else that it is due to some of the other products of waste which are not properly eliminated from the system. It is possibly due to the development of ptomaïnes.

Dr. Hugh Blair, of Richmond, Va., had long since come to the conclusion that the form of vertigo described is due mostly to lithæmia, and that lithæmia is but another expression for gout, and that it is all due to disordered fermentative digestion, due to the imperfect liver action.

Permanent Drainage of the Male Bladder by a Retained Cannula introduced above the Pubes.—Dr. George Benjamin Johnston, of Richmond, read a paper with this title. He said that Dr. Van Buren had devised the best instrument for the purpose that he knew of, consisting of an outer cannula, an inner tube, and a trocar. After quoting descriptions of these, Dr. Jonnston stated that he had added to this instrument a steel guide, double the length of the trocar, over which the outer cannula may be easily drawn out of the bladder and replaced without fear of losing its course. After describing the simple operation of entering the bladder above the pubes, and how to retain the instrument, he remarked that both acute and chronic cases are benefited by the proposed treatment. Conditions so benefited are urinary retention, injuries of the urethra or prostate, acute prostatitis, perineal abscess, urinary extravasation, coagula in the bladder, chronic cystitis, enlarged prostate, or cancer of this gland or of the bladder, urinary fistulæ, sacculations, adynamia, etc. After pointing out nine distinct advantages of the operation, he gives a paragraph of cautions to be observed in performing the operation, etc.

The Present Status of Abdominal Surgery.—Dr. Joseph Price, of Philadelphia, Pa., read a paper on this subject. The abdominal surgeon should be prepared for the unexpected—for packing the whole pelvis or for removing a kidney or the uterus. Hence he should be a specialist. Vaginal puncture is a dangerous procedure, because it cannot be predicted what organs are involved in the abscess wall, or the abscess may be multiple, etc. Nearly every pelvic abscess takes its origin from a diseased tube or ovary. Hence the abdominal incision is best. To remove fibrocysts of the uterus, if carefully performed, shuts off the peritoneal cavity from the surrounding tissues, a technique which must be freed from every loophole of error. The great essential in the instrumental technique of the operation is the use of the clamp or *serre-nœud*. To the clamp belongs the credit of giving to hysterectomy its acknowledged position. By its use he has performed twenty-seven hysterectomies without a death. Each stump must be made according to the exigencies of the case. In general, free the bladder, save the peritoneum, dissect out the tumor until sufficiently free to engage it with a clamp. As to the after-technique, close the pelvic peritoneum, and embrace the stump by the parietal peritoneum, so as to close off the peritoneal cavity absolutely. The mortalities of dabblers in abdominal surgery should not be considered. The Porro operation is preferable to the Cæsarean. As to ectopic pregnancy, operate as soon as the condition is discovered. He has had now an operative experience of thirty-eight cases, but has never seen an intraligamentous variety of this condition. Always remove the placenta when possible. If compelled to leave it, empty it of blood, make it as dry as possible, tie the cord close, and tie the stump. The peritoneum will probably digest it. In all cases of prolonged operation, especially in threatened shock, and after hemorrhage, and in the presence of pus and *débris*, the value of flushing out the cavity with moderately hot water is beyond question. In those cases characterized by overwhelming quantities of pus there is no need whatever of using antiseptics. Pure or distilled water thoroughly cleanses the abdomen, lowers temperature, slows the pulse, etc. In all abdominal surgery germicides are useless, and may be harmful; the same may be said of opium, except where the opium habit has already been acquired. In after-treatment allow no food or drink until the stomach is entirely settled. Then begin liquid diet in small quantities—buttermilk being an excellent initiative. If there are signs of tympany, a saline purgative will usually afford prompt relief; or if this is not well borne, use small doses of calomel. As a preparatory treatment for operation, insist on rest in bed for at least twenty-four hours, and free purgation. Keep patient in bed at least three weeks after a lapa otomy, which will obviate hernia in most cases. He has not much faith in the so-called electrical treatment of abdominal tumors.

Early Exploratory Incision as an Aid to the Diagnosis of some Surgical Diseases of the Abdominal Cavity.—Dr. Edwin Ricketts, of Cincinnati, read a paper with this title. He had found it difficult in many cases to make a diagnosis previous to exploratory incision. To open the abdomen was easy enough, but afterward to do always the best thing, and that promptly, knowing when to end at exploration, bearing in mind that half-completed surgical procedures are rarely ever excusable, these are of greatest consideration. He did not deny that a diagnosis cannot be made previous to an incision in some cases; but in a majority we cannot make out with any degree of certainty until, Thomas-like, we first see and feel the condition present. He claiming that the one from the outside that is always sure of what is on the inside is the one, with his occasional operations, who is placed in a humiliating attitude before his guests, and is liable to attempt the completion of an operation that may be wholly unwarrantable. The undue conservative physician, with his free use of opiates, has grave responsibilities, for the reason that his prompt efforts for the relief of pain too often postpone the recognition of needed surgical interference. He reported briefly eleven cases, coming under his observation, where exploratory incision was necessary to diagnosis.

Nervous Disorders following Organic Strictures of the Urethra.—Dr. Hunter McGuire, of Richmond, related a number of cases in which paralysis, apoplexy, or cerebral disease of some kind followed long-standing stricture. In some of these cases there was renal disease. In his practice he had seen sclerosis of some portion of the spinal cord follow old strictures. He concludes the paper thus: "Are all of these cases mere coincidences? Urethral strictures are so common, and diseases of the nervous centres so frequent after middle life, and the interval of years between the formation of the stricture and the appearance of nervous troubles so great that it is difficult to say that one is dependent upon the other. As it is, however, I cannot help thinking that long-existing urethral strictures may set up reflex irritation in one or more of the nervous centres, and this persisting ends in pathological change in one form or another."

The Salient Points in Appendicitis—Its Diagnosis and Treatment.—Dr. Joseph Hoffman, of Philadelphia, Pa., read a paper on this subject. The cæcum hangs more or less free in the abdomen, and hence has considerable latitude as to motion, while the appendix varies in position according to the movement of the cæcum. There is frequently a dependent pouch between mesentery of the appendix and the ileum, consisting of folds of the peritoneum, which, from pressure of the rotation of the cæcum, becomes either congested or atrophied, and is thrown into a band—in either way becoming a source of danger to near-lying intestines, either as a strangulating cord or as a ring through which a fold of intestine may fall and be choked in a hernial fashion. Thus it is evident that a purely physiological rotation of the cæcum may bring on a pathological congestion without the presence of any irritating matter whatever. But keep in mind that although the position of the appendix is variable, it is not abnormal, but depends entirely upon the rotary movements, above referred to, of the cæcum. This fact will be useful in determining approximately the position of the appendix, and thus shorten the operation and prevent unnecessary handling of the intestines.

As to treatment, surgeons are divided into three classes: 1, Those who operate at once upon the occurrence of induration, pain, and high temperature; 2, those who wait, on the ground that a great majority recover under rest and opium; and 3, those who operate between attacks, or who wait for recurrence. This last class represents the progressive surgery of to day, and includes such surgeons as Senn and Treves. But of course individual surroundings must have their due weight in determining when to operate. As to the plan of operation, be led by the principles of abdominal, not general, surgery. Mr. Treves, Dr. Homans, etc., are wrong in condemning the drainage-tube, as the results of Tait and hundreds of other abdominal surgeons prove. In women, in general terms, the best advice is to cut through the median line, for the chances are that in them the disease will not be found to be appendicitis, while if needed it has advantages anyhow.

As to diagnosis, exploratory incisions are often resorted to when symptoms point to the presence of pus; but Dr. Hoffman thinks they should be condemned. In men, the presence of an indurated mass in the right iliac fossa, with detection of pain and fulness in the region by rectal examination, is important. The right leg is often drawn up.

Remarks upon Anteflexion of the Uterus.—Dr. George Tucker Harrison, of New York, presented a communication on this subject. The normal position of the uterus in the erect woman, when the bladder and rectum are empty, is that of anteversio-flexio, the place of flexion being at the junction of the cervix and body. But when the bladder is distended the uterus is lifted up physiologically, and its posterior wall lies in juxtaposition with the anterior wall of the rectum; it is both retroposed and retroverted. While the bladder is being emptied, the fundus uteri describes an arc which corresponds to an angle of from forty-five to sixty degrees. The characteristic feature of pathological anteflexion is simply the stability of the flexion. The causes which make the flexion permanent are either in the organ itself, or operate on it from without. Metritis or infarction belong to the first class of causes, while parametritis posterior, or parametritis chronica atrophicus, or perimetritis belong to the second and more frequent and permanent in effects class of causes. When metritis attacks an anteflexed uterus, the angle which, up to that time had been variable, becomes fixed. The symptoms usually associated with anteflexion are dysmenorrhœa and sterility. This painful dysmenorrhœa is not mechanical, but is due to the associated metritis. The sterility, also, is attributable to the accompanying endometritis, oöphoritis, and perimetritis. If these inflammations are removed, and if the perimetritis has left no permanent pathological changes, conception may ensue, notwithstanding the existence of parametric cicatricial tissue or permanent anteflexion. The diagnosis of this pathological anteflexion depends alone on the demonstration of the stability of the flexion. Bimanual palpation, or the establishment of the fact that the anteflexion persists even when the bladder is distended, or the discovery that the folds of Douglas's sac are shortened or thickened, are the means for deciding the stability or non-stability of the flexion. As to treatment, it is of prime importance to try to remove the parametritis posterior or perimetritis and results. If the uterus is supersensitive, scarify it just prior to menstruation, and the dysmenorrhœa will be moderated. For the persistent uterine catarrh, wash out the uterine cavity with a solution of carbolic acid after dilatation with aseptic laminaria tents, followed by steel dilators. Lately he has been very much pleased with ichthyol, incorporated with lanolin, applied around the portio vaginalis, in clearing up old peri-arid parametric adhesions.

Epilepsy.—Dr. M. D. Hoge, Jr., Richmond, Va., next read the report on "Advances in Neurology," confining his remarks more especially to epilepsy. He said that the treatment was a combined one, the nutrition of the anæmic brain is best supplied by cod-liver oil containing the hypophosphites of lime and soda. The use of atropine controls, in many cases, the severity of the muscular contractions, and undoubtedly lengthens the interval between the aura and the convulsion itself, thereby allowing the patient time to take some sedative and possibly suppress the attack. Bromides are best given, as Seguin first suggested, with chloral. They cannot be dispensed with entirely during the first few months of treatment. They should always be conveniently within reach and taken instantly on the first premonition of an impending attack. All sources of external irritation from any reflex cause must be at once corrected. The improvement is usually slow at first, but in every case of the non-traumatic variety where it has been used the results have been perfectly satisfactory.

Vaginal Extraction of a Vesical Calculus.—Dr. E. M. Magruder, of Charlottesville, reported a case of "Removal of a Large Vesical Calculus per Vaginam." The stone was about two by three inches, and had caused a fistulous opening of about five-eighths of an inch diameter in the vaginal wall. The doctor reported the steps of the operation adopted for its removal by enlarging the vesico-vaginal opening, and as the stone seemed adherent, pieces of it had to be removed at a time, instead of by lifting it out of its pouch.

Dr. L. Ashton and Dr. Oscar Wiley, the retiring President, were elected honorary fellows. The Society then adjourned.

Erratum.—In Dr. Baruch's Paris letter, page 423 of the Medical Record, October 11, 1890, fourth line from bottom of first column, it should read "of an average of 2.7 per cent., instead of twenty-seven per cent." The dot is small, but the difference it makes considerable.

Correspondence.

THE EDUCATION OF THE SENSE OF SMELL.

To the Editor of the Medical Record.

Sir: In reading your editorial on the education of the senses, and especially noting what you say about the smell, it occurs to me that I have never seen in print the reasons why the sense of smell, which is really so delicate and often so precise and accurate, is so difficult to utilize systematically for purposes of diagnosis.

It is true that very small quantities of odoriferous substances and many organic impurities may easily be recognized by this sense; but they soon cease to make an impression unless the nose can be refreshed by recurrence to pure air.

In other words, for clear perception we need a background or neutral term of comparison, and this it is more difficult to obtain for ready reference in the case of odors than with sight and sound.

The chief reason, however, for the little knowledge we have of certain smells is the impossibility of recording observations upon them accurately, and hence the impossibility of accumulating experience, upon which nearly all clinical observation rests, except so far as each individual's opportunities go, and many human individuals undoubtedly acquire very considerable powers in this way. We know well the much greater powers of some lower animals. Visual objects can be accurately described and recorded so as to be again recognized, and sounds not quite so well; but smells can only be vaguely described or compared with some other universally known odor.

Large numbers of odors are highly characteristic and unmistakable, but there are others less frequently met with, where, from the impossibility of description, different observers cannot compare notes, and opportunities are too few in one person's experience to lead him to important conclusions.

The smell of small-pox, for instance, is highly characteristic, but I presume it would have little value in diagnosis for a great many of the graduates of the last five, or possibly ten, years, who have never seen or smelt a case, and it would be as impossible for an instructor to inform them of its peculiarities as to enable them to recognize for the first time a heliotrope without seeing it. In the latter case, however, one could make some use of the crude imitations which are sold by the apothecaries under the name of that flower.

The smell of pyæmia is described as "sweetish," which certainly does the student no good until he has smelt it.

I have twice or three times in my life encountered a certain smell, not especially far-reaching, in the breath of persons whom I met accidentally, so peculiar that I am almost sure it must have some diagnostic significance; but as I knew nothing of these people except that they looked sick and anæmic, and I cannot learn more, as I have no means of ascertaining whether anybody else ever smelt the same thing.

Osmology awaits its scale of tones or colors. Who will be its Helmholtz or its Kirchhoff? All this only emphasizes your remark about the importance of training the senses; but if it were possible to accumulate and transmit experience in matters of smell as we do in matters of sight, sound, and touch, I feel sure that the possibilities of ready diagnosis would be considerably enlarged.

Yours very truly,

Schneider.

Chattanooga.—A new hospital is being planned for Chattanooga. A company has been formed of sufficient strength to assure its erection and equipment with all the modern appliances for the comfort of patients and quick and easy manipulation of the surgeons. In connection with the hospital will be a medical college.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 5 to October 11, 1890.

Vollum, Edward P., Colonel and Surgeon. To be Chief Medical Purveyor, with the rank of Colonel, August 28, 1890.

Irwin, Bernard J. D., Lieutenant-Colonel and Assistant Medical Purveyor. To be Surgeon, with the rank of Colonel, August 28, 1890.

Fryer, Blencowe E., Major and Surgeon. To be Assistant Medical Purveyor, with the rank of Lieutenant-Colonel, August 28, 1890.

Cowdrey, Stevens G., Captain and Assistant Surgeon. To be Surgeon, with the rank of Major, August 28, 1890.

Taylor, Arthur W., Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from duty at Fort Wingate, N. M., to take effect on the expiration of his present sick leave of absence, and will report in person to the commanding officer at Fort Adams, R. I., for duty at that station, relieving Captain J. J. Cochran, Assistant Surgeon. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

Cochran, J. J., Captain and Assistant Surgeon. By direction of the Secretary of War, on being relieved by Captain Taylor, will report in person to the commanding officer at Camp Eagle Pass, Tex., for duty at that station, relieving First Lieutenant Paul Clendenin, Assistant Surgeon. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

Clendenin, Paul, First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, on being relieved by Captain Cochran, will report in person to the commanding officer at Fort Brady, Mich., for duty at that station. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

Reed, Walter, Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from further duty at Mount Vernon Barracks, Ala., and assigned to duty as Attending Surgeon and Examiner of Recruits at Baltimore, Md. S. O. 232, par. 7, A. G. O., Washington, D. C., October 4, 1890.

Gibson, Robert J., Captain and Assistant Surgeon. By direction of the Acting Secretary of War, granted leave of absence for three months, to take effect on being relieved from duty at Fort Trumbull, Conn., by Major Henry M. Cronkhite, Surgeon. S. O. 232, par. 12, A. G. O., Washington, D. C., October 3, 1890.

Benham, Robert B., Captain and Assistant Surgeon. By direction of the Secretary of War, will proceed from Fort Hamilton, N. Y., to Mount Vernon Barracks, Ala., and report in person to the commanding officer of that post for temporary duty, relieving Captain John J. Cochran, Assistant Surgeon, who will return to his proper station. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 11, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	33	14
Scarlet fever	30	1
Cerebro-spinal meningitis	1	3
Measles	59	4
Diphtheria	47	18

EXPERIENCE WITH SKIN-GRAFTING AFTER THE METHOD OF THIERSCH.[1]

BY CHARLES McBURNEY, M.D.,

SURGEON TO THE ROOSEVELT HOSPITAL, NEW YORK.

WHEN Reverdin, in 1870, first brought before the profession the method of skin-grafting, well known now all over the world by his name, an extremely valuable addition to our surgical resources was made. By its aid surgeons have been able, in innumerable cases, to procure sound healing of extensive ulcerated surfaces, which without it would have remained permanently open, and in a much larger number of cases have they very materially hastened the cicatrizing process. This method is one with which all are so familiar that, at the present time, the very briefest description of it is sufficient.

Given a large ulcerated surface, as that resulting from a burn, and one which has reached a stationary condition, attempts at further cicatrization having ceased; small bits of the superficial layers of healthy skin are removed with curved scissors from the patient himself, or from another individual, and are immediately transferred to the ulcerated surface. The bits of skin are usually about the size of a canary-seed, although considerable variations in size may be safely made. These are carefully placed upon the previously disinfected granulations, always with the raw surface downward, and are gently pressed, so that they will lie flat and firm. Many such grafts may be made at one time, the number being only limited by the size of the ulcer and the patience and strength of both patient and surgeon. An appropriate dressing is then applied, and changed from day to day; and while some of the grafts will disappear, many will become adherent, will receive a supply of nutriment from the vascular granulations below, and will rapidly extend their areas, appearing to have the effect upon neighboring granulations of stimulating the formation of firm epithelium. When cicatrization ceases to advance, a second grafting may be done on other granulations, and this may be repeated again and again until the entire surface is covered with a horny surface. As already stated, this was a very valuable addition to surgical resources, and has accomplished an immense amount of good; but it is a slow and laborious process, not infrequently unsuccessful, and applicable only to granulating surfaces which have been previously brought to a properly healthy condition. The method of skin-grafting suggested by Thiersch was brought before the profession only a few years after Reverdin's first publication, and has been constantly made use of ever since that time at Thiersch's clinic, in Leipsic.[2] Many surgeons are familiar with it, and yet, if I may judge from the limited number of publications on the subject, and from the comparatively few reported cases of its use, the method has not yet been generally fully appreciated, nor has the knowledge of it spread as far as it deserves. I did not myself estimate the method at anything like its real value until I visited Thiersch's clinic and witnessed the wonderful results he was frequently attaining. Since that time I have neglected no opportunity to apply the process in suitable cases, and in doing so I have been most ably assisted at the Roosevelt Hospital by Dr. Hartley and the members of my house staff, all of whom are deeply interested in the subject. Beginning with the original method of Thiersch, we have endeavored so to modify it, as to reduce the labor of the dressings and to increase their efficiency. It is with a view of presenting the results of our practical work, that I am reading this paper to-night.

According to Thiersch, all strong antiseptics are to be avoided in skin-grafting, as the effect of these upon the cellular elements, upon the capillaries, and upon the blood itself, is such as to seriously endanger, and even totally prevent, the immediate union between the grafts and the surfaces upon which they are placed. Thiersch himself uses absolutely no solution excepting one of common salt in water, in the proportion of six parts to one thousand, or about one and a half drachm to the quart. I am convinced that it is important that this solution should be sterilized. The water used should be distilled and the solution should be boiled just before using. My own practice has been to use a solution of bichloride of mercury freely in disinfecting the ulcerated surface, and also the surface from which grafts are to be taken, afterward completely washing away all of this solution with the saline one of Thiersch just before operating. I have also used soap and water thoroughly in beginning the cleansing process. All hair should be removed from the areas involved by careful shaving. In some cases grafts may be placed with success directly upon the unbroken surface of healthy granulations, but a much more certain method of securing success, and, according to Thiersch, one essential to the avoidance of subsequent contraction, is to remove, by curetting, the superficial layer of granulations and also the tough cicatricial edge of the ulcer. A bleeding surface is thus produced on which many open capillaries exist, and which is very favorable to the immediate union of the grafts. To bring about the same result I have found it more rapid and convenient to use the knife. With a sharp scalpel an incision nearly or quite through the true skin is rapidly made entirely around the ulcer, just outside of its thickened border. With the same instrument the whole area included by the incision, that is, the granulating surface and thick edge, is shaved off with great ease and rapidity. A smooth, bleeding, healthy surface of a considerable depth is thus produced. This surface is immediately irrigated with the sterilized salt solution, and compresses of sterilized gauze are pressed upon it to control bleeding. The question of hemorrhage at this stage in the operation is one of considerable importance. If grafts are placed while bleeding still goes on, the risk of failure is much increased. Accumulations of blood, even small ones, beneath the grafts frequently induce their necrosis, and saturation of the dressings with blood is favorable to infection. But all ulcerations, and particularly those on the lower extremities, when shaved, are liable to bleed actively for a long time; so long a time, indeed, as to sometimes seriously endanger the patient's condition, or at least to wear out the surgeon's patience. E. Fischer made the observation that grafts united more readily when Esmarch's constricting band was applied above. I feared at first that the complete anæmia thus induced might endanger the vitality of the grafts. I have found, however, that the use of Esmarch's band entirely disposes of the question of hemorrhage, shortens the whole operation very greatly, and does not in the least affect the vitality

[1] Read before the New York Academy of Medicine, October 2, 1890.
[2] G. R. Fowler: Annals of Surgery, 1889, p. 179.

of the grafts. When, therefore, the situation of the ulcer is such that the band can be applied, it is put on above the whole field of operation, thus rendering the process a nearly bloodless one. The grafts may then be immediately applied and the dressings put on. After operating upon the extremities they should be placed in an elevated position to favor hæmostasis. In several instances I have allowed the Esmarch band to remain on the limb for an hour or more after the operation was finished, and always with a favorable result. If vessels of sufficient size to require special treatment are opened, they should be closed by torsion rather than by the ligature. The knot of ever a fine catgut ligature prevents close adaptation of the graft at that point.

The grafts themselves illustrate most remarkably the originality of Thiersch's method. They consist of thin slices removed by shaving parallel with the surface. They may of course be taken either from the patient or from another individual. I have myself always used the patient's own material. Any broad knife may be used in cutting the grafts, but no instrument is so good as a broad razor with a very delicate edge. With this instrument, shavings no thicker than a sheet of note-paper, four or five inches long and an inch broad, may with a little practice be readily made. The surface from which grafts are to be taken should have been thoroughly cleansed and shaved, and then be wet with the salt solution. The most favorable and convenient points are the front and outer parts of the thigh, and the outer surface of the upper arm. If the surface to be grafted is upon the head or neck, the upper arm of the same side should be selected for the grafts. If the leg is to be grafted, the thigh on the same side is most convenient. If the breast or abdomen is to be grafted, the thigh also furnishes the grafts most conveniently and in the largest quantity.

The operator should stand facing the patient. With his left hand grasping the limb from below, he stretches the skin snugly about the limb. His assistant, using both hands, stretches the skin from above downward. It is impossible to take good grafts from a lax surface. Taking the razor in the right hand, the operator wets it in the salt solution, and applying the edge at the most distant part of the stretched skin, with a rapid shaving motion toward himself shaves off as thin and long and wide a shaving as he can. Four or five inches in length and an inch wide are about the dimensions of a first-rate graft. In regard to thickness, considerable variety may be safely indulged in. Some grafts may be as thin as tissue paper and others as thick at some parts as card board. All will do well, but no graft will do well that is so thick as to have fat upon its under surface. While cutting the graft folds up upon itself on the surface of the razor, and when a sufficient length has been reached the edge of the razor may be turned outward and the graft so severed from its connection with the skin, or, generally more conveniently, an assistant will sever it with scissors. If the graft is once dropped from the razor great difficulty is met with in handling it. If this accident happens, it takes less time to cut a new graft than to rearrange the old one. The graft being then piled up on the razor, a few drops of salt solution should be dropped on it and the instrument be immediately carried to the edge of the surface to be grafted. With a probe, one end of the graft may be slid off the razor to the raw surface, and being held there, the razor may be slid from under it across the surface, so as to unfold the graft and deposit it in place. If not exactly in place, it may readily be slid about with two probes until it lies accurately in position. The graft should be so placed that its end will follow up the perpendicular edge of the prepared surface, and reach very slightly onto the uncut skin. In this manner graft after graft is placed, great care being taken that their edges are in neat apposition to one another and are at no point folded under. From time to time a little salt solution should be sprinkled on the grafts already placed, that they may not become too dry. The entire surface to be grafted should be covered. Moisture is absolutely essential to the continued vitality of the transplanted skin; therefore a dry dressing is inadmissible. Strips of Lister protective or of thin rubber-tissue, about an inch wide and long enough to a little more than cross the grafted surface, should then be laid like shingles, overlapping one another over the entire area. These strips should have been sterilized in the bichloride or carbolic acid solution and then drawn through the salt solution. They should be gently pressed flat upon the grafts.[1] Any soft sterilized material may be used as a compress over the protective, but nothing is better than loose handkerchiefs of sterilized gauze. A mass of this material, wet with the salt solution, should be piled up over the protective or rubber tissue to prevent rapid evaporation, and finally a well-applied gauze bandage.

The surface from which grafts have been taken now requires attention. Up to a recent period I have habitually treated this surface by dusting it with iodoform, and covering that with iodoform and bichloride gauze. With one exception, which will be referred to later, this surface has always healed well, but it has often been quite painful, and has frequently required a longer time to heal than the grafted surface itself. One of my assistants, Dr. Schultze, recently suggested that this surface be wet with salt solution, and then be completely covered simply with rubber-tissue, with sterilized gauze above. This method has given great satisfaction, healing going on very rapidly and entirely painlessly. In a recent case, a very large surface on the thigh from which grafts had been taken was treated in this manner and was entirely healed on the eighth day.

I have made no mention as yet of the use of anæsthetics while performing this operation, and I notice that the writer of a recent article on this subject expresses a fear that they may act unfavorably on the grafts. I have used ether in every case operated upon, and so far as I can see, without the slightest unfavorable effect.

The variety of lesions to which Thiersch's method is adapted is very large. It includes all ulcerated surfaces upon any part of the external surface, and the process is destined, I am very sure, to displace all of the older methods, many of which are in constant use to-day. Varicose ulcers, ulcers produced by burns, by extensive wounds, by sloughing processes, can be all rapidly and successfully healed by this method. But those who are not familiar with the method would be surprised to see how perfectly and successfully these grafts can be immediately applied to the denuded surface produced by extensive operations for the removal of malignant and other tumors—to any raw surface, in fact, which cannot be covered by the adjacent skin. How often it happens that the complete removal of a cancerous breast, particularly in secondary operations, or the excision of a broad tumor from the head or face, necessarily leaves a very large exposed surface to heal by the slow process of granulation and cicatrization. In not a few cases malignant disease reappears before the wound produced by operation has healed, to the disgust of the surgeon and the despair of the patient. Upon such surfaces grafts may be placed as soon as the primary operation is finished and hemorrhage has ceased. And it is astonishing to see the variety of tissue to which the grafts will firmly adhere. Muscle, fascia, cartilage, and even bare bone, may all be successfully grafted. The most favorable surface is a clean muscular one, and the least favorable the surface of compact bone. In one case, after the removal of an extensive carcinoma of the face, a large area of lower jaw was completely bared. Grafts laid over this surface adhered nearly perfectly throughout, and at the end of a week those that covered the bone were found to be soundly attached to it. In another case, a surface several inches in diameter on the back of the forearm included a number of exposed extensor tendons.

[1] Strips of rubber-tissue are used rather than a single larger piece, in order that the salt solution with which the gauze is wet may more readily reach the grafts.

The grafts applied in this case were more than usually successful, and complete healing was rapidly attained. The breast cases have especially interested me, and I have come to feel entirely at liberty to make extremely wide and thorough removal of disease in this situation, knowing that I could at the same time cover the surface, without resorting to any plastic operation by sliding flaps, and without running the risk of having to treat a large ulcer for many months after operation. The method adopted in the breast cases has been as follows: First, as complete a removal of disease, including as much surrounding skin as seemed desirable to avoid recurrence. Then a closure by suture of such parts of the wound as could be sutured without too great tension.

There would still, perhaps, be left an exposed area of chest-wall of from four to six inches diameter. The depth of this wound I have diminished by a considerable number of catgut sutures so applied as to partially invert the skin edge, and bring these down nearly to the muscular level. Upon this diminished and shallow wound the grafts have been laid so as to entirely cover it. The wound has then been dressed in the manner already described, and the arm, bent at a right angle at the elbow, bound to the thorax. After the primary dressing, the management of the cases has been varied gradually from the original method. I learned from Thiersch that the gauze placed immediately over the protective should be kept constantly moist with salt solution, and that to effect this it was necessary to moisten the gauze every four hours. This was a very laborious process, and I have gradually extended the time between the applications of salt solution, until now it is done only once in two days. This seems sufficiently often, and the cases treated in this manner have done perfectly well. At the end of forty-eight hours, then, the dressings are all removed excepting the protective, which lies next to the grafts. A fresh wet dressing is applied and changed again after two days. By this time there is usually some formation of pus, or at least of a purulent-looking exudation; in fact, I have seen no case go on for a whole week without any pus. If it exists in considerable quantity it is removed by absorbent gauze, and the protective removed and fresh material applied. The protective may be lifted and the grafts examined without danger at any time after the second or third day. If successful they look smooth and pink, and if unsuccessful at any part they look shriveled and yellow or brown, and may die at some points. But even when only partially successful, the granulating spots have quite rapidly healed over under ordinary treatment. A dry dressing applied too soon to the grafts destroys their vitality through the absorption of moisture, and we have made it a rule to leave the protective in place for from ten to fourteen days. At the end of this time the protective has been removed and an ordinary antiseptic dressing applied; granulations, when exuberant, being touched with nitrate of silver, or dressed with balsam of Peru.

Case I. *Large Indolent Ulcers originating in an Extensive Suppurative Prepatellar Bursitis.*—M. B.——, a male, forty years of age, entered the Roosevelt Hospital on December 30, 1889. Persistent treatment totally failed to diminish the ulcerated areas.

February 15, 1890.—Esmarch's constricting band applied just below the left groin. The surfaces of the ulcers, three in number, were shaved, and the edges completely excised. Grafts taken from the left thigh were applied, then the dressing already described, the limb was elevated, and the patient sent to bed with the constricting band still on. The band was removed a few minutes later.

March 4th.—Grafted areas all soundly healed, excepting that a few very small granulating spots remain.

March 16th.—Healing complete.

Case II. *Extensive Recurrence of Carcinoma in and about the Cicatrix left by a former Operation on the Left Breast.*—Mrs. S——, aged forty. August 20, 1890. A very free excision of all diseased tissue was made. A few sutures were applied at the inner and outer angles of the wound, but an open area about five inches in diameter remained uncovered. To this surface grafts taken from the left thigh were applied on September 16th. The entire surface was soundly healed.

Case III. *A large Epithelioma of the Malar and Anterior Temporal Regions of the Right Side of the Face.*—Miss M——, forty-one years of age, came under my care in April, 1889. The notes of this case have been lost, but after excision of the tumor the exposed surface was large and deep. Cicatrization was very slow, and in May, 1889, grafts were applied to the entire surface. The operation was very successful. I saw the patient this morning, and the grafted surface is perfectly smooth and sound.

Case IV. *Large Cysto sarcoma of Right Breast.*—Mary B——, aged fifty two, entered the Roosevelt Hospital on June 29, 1890.

July 6th.—The tumor was removed by free excision, no available skin remaining to cover the exposed surface left, which measured four by five inches. A few sutures at the angles of the wound were applied. Grafts taken from the right thigh were immediately applied. In this case only about half the grafts were successful. The whole wound was soundly healed on August 26th.

Case V. *Lupus of the Cheek Measuring three by two and one-half inches.*—Ellen H——, aged thirty-eight, entered the Roosevelt Hospital on August 4, 1890.

August 8th.—Complete excision of the disease. Grafts were immediately applied from the right thigh.

September 1st.—Complete healing had occurred. In this case the new surface is decidedly keloid in character.

Case VI. *Large Varicose Ulcer over Inner Malleolus of the Left Ankle.*—Eliza E——, aged forty-six, entered the Roosevelt Hospital on June 3, 1890. Margin unhealthy and base sloughy.

June 13th.—The ulcer was completely excised. Grafts from the thigh immediately applied.

July 22d.—Complete healing had occurred.

Case VII. *Recurrent Sarcoma of the Right Breast.*—E. S. M——, aged forty-three.

May 29, 1890.—Thorough extirpation of diseased tissue, leaving an open surface measuring about five by four inches. Immediate grafting from the right thigh.

On June 29th a few minute granulations remained. The rest of the surface had healed.

Case VIII. *Large Indolent Ulcer on Left Leg.*—F. L——, forty six years of age, entered the Roosevelt Hospital on July 17, 1890. The ulcer was about ten inches long and two inches wide. It had existed for eight years.

July 18th.—The ulcer was excised, and grafts from the left thigh were immediately applied.

August 6th.—Completely healed. (Patient exhibited.)

Case IX. *Large, hard, Ulcerated Carcinoma of Right Breast.*—Mary C——, forty-five years of age, entered the Roosevelt Hospital on June 19, 1890.

June 27th.—Extensive removal, leaving a surface which measured five inches in diameter, and which could not be covered by any ordinary means. Immediate grafting from the right thigh. About half of these grafts failed, doubtless owing to the fact that the first dressing was left unchanged, as an experiment, for five days.

August 12th.—The entire grafted area was soundly healed.

Case X. *Highly developed Condition of Ectopion Vesicæ.*—W. W——, five years of age.

November 19, 1889.—Wood's flap operation was done, and to diminish the raw surfaces left sutures were applied wherever they could be useful. A large uncovered wound still remained, which was immediately grafted from the thigh.

December 10th.—The entire surface was healed.

Case XI. *A large Ulcer of the Leg originating in an Extensive Injury.*—J. D——, aged nineteen, entered the Roosevelt Hospital on October 19, 1889. The ulcer

had existed for six years, and had received much treatment.

December 28th.—The surface of the ulcer was shaved and grafts applied.

January 20th.—Three small points of granulation only remained open.

February 12th.—The whole surface was firmly closed.

Case XII. *Flat Ulcerated Epithelioma of Left Forearm.*—Mary G——, aged sixty, entered the Roosevelt Hospital on July 5, 1890.

July 11th.—Complete excision, leaving a surface which measured four by five inches. Grafts were immediately applied from the left thigh.

August 5th.—Complete healing had occurred.

Case XIII. *Large Sarcoma of Left Breast.*—H. N——, aged fifty, entered the Roosevelt Hospital on June 4, 1890.

June 6th.—Complete and free excision, leaving an exposed surface measuring about five inches in diameter. Grafts from the left thigh were applied.

July 21st.—The entire surface had healed.

Case XIV. *Very large Carcinoma of the Left Breast.*—C. F——, aged forty-four, entered the Roosevelt Hospital on July 10, 1890.

July 11th.—Complete removal of the tumor. The uncovered surface which remained measured five by four inches. Grafts from the left thigh were applied.

August 5th.—The wound had completely healed.

Case XV. *Extensive Laceration of the Right Forearm, resulting in an unhealthy Ulcer Measuring three by five inches.*—A. W——, aged fifty, entered the Roosevelt Hospital on March 21, 1890.

April 23d.—The ulcer was shaved and grafts from the thigh were applied.

May 4th.—Only a few minute points of granulation remained.

Case XVI. *Carcinomatous Ulcer of the Left Cheek, about one and one-half inch in Diameter.*—J. M——, fifty-six years of age, entered the Roosevelt Hospital on January 24, 1890.

January 25th.—Complete excision and grafting.

February 17th.—Completely healed, excepting one minute granulating spot.

Case XVII. *Extensive Burns of Penis, Scrotum, Left Thigh and Back.*—W. O——, fourteen years of age, entered the Roosevelt Hospital on July 2, 1890. Immediate treatment, carbolized oil, etc.

August 8th.—Three unhealed ulcers remained, the largest being on the antero-internal surface of the left thigh. This ulcer measured eight by six inches. Grafts taken from the right thigh were applied.

September 1st.—Two small areas of granulation, the size of a quarter of a dollar, were the only unhealed points. These were dressed with balsam of Peru.

Case XVIII. *Keloid over the Right Patella, and Indolent Ulcer following Suppurative Bursitis.*—M. D——, sixteen years of age, entered the Roosevelt Hospital August 4, 1890.

August 6th.—An area measuring two and one-half by one-half inch was excised, grafts from right thigh immediately applied. Complete healing occurred on September 12th.

Case XIX. *Ulcer on the Inner Aspect of Right Leg.*—B. C——, nineteen years of age, entered the Roosevelt Hospital on August 14, 1890. The ulcer had existed for one year, and measured one and one-half by one and one-quarter inches.

August 15th.—Grafts from the right thigh were applied.

September 15th.—Entirely healed.

Case XX. *Large unhealthy Ulcers of Right and Left Legs, Measuring four by five inches.*—Ira F——, aged twenty-nine, entered the Roosevelt Hospital on December 15, 1889. One of these ulcers had existed eighteen years. Preliminary antisyphilitic treatment.

January 23d.—No improvement having occurred, the ulcers were shaved, the edges excised, and grafts from the thigh immediately applied.

February 15th.—The entire ulcerated surfaces were healed, with the exception of one spot of granulation the size of a three-cent piece.

This patient developed erysipelas in the surface from which the grafts had been taken, and was transferred to the pavilion at Bellevue. He recovered from his erysipelas and left Bellevue subsequently, entirely well.

Case XXI. *A Prominent Circular Epithelioma of the Size of a Silver Half-dollar, situated on the Right Lower Eyelid.*—E. W——, aged thirty-nine, entered Roosevelt Hospital on June 2, 1890.

June 6th.—The tumor was excised without cutting the cartilage of the lid. A single graft from the arm was applied to the exposed surface.

June 13th.—Complete and sound healing had occurred. The surface was smooth, and only differed from the surrounding integument in being slightly darker in color.

Case XXII. *Epithelioma, two inches in Diameter, over Right Temporal Region.*—A. S——, fifty-nine years of age, entered the Roosevelt Hospital on December 10, 1889.

December 21st.—Complete excision, leaving a surface measuring three by four inches. Grafts from right thigh immediately applied.

January 12th.—Completely healed, excepting a few granulating spots.

Case XXIII. *Ulcerated Carcinoma of Right Breast.*—R. R——, forty-four years of age, entered the Roosevelt Hospital on April 25, 1890.

April 26th.—Complete removal, leaving an uncovered surface measuring about four inches in diameter. Grafts from left thigh applied. About half the grafts failed to unite. This patient was lost sight of May 14th, with the surface largely healed.

Case XXIV. *Large Carcinomatous Ulcer of the Left Side of the Neck and Face.*—J. F.——, forty-three years of age.

December 28, 1889.—An extensive dissection was required to remove the disease, and a deep cavity measuring three by four inches was left after the excision. The descending ramus of the lower jaw was extensively bared, and also the mastoid process and the large vessels of the neck. Grafts to cover the whole surface were taken from the left upper arm; all of these grafts adhered perfectly, even those applied to the exposed bone, with the exception of an area about one inch in diameter next to the ear.

January 21st.—Almost the entire surface was soundly healed. The patient was then lost sight of.

I have reported here twenty-four cases, representing a considerable variety, both as regards the size and the character of the surface grafted. Most of the patients were ordinary ward patients received into the Roosevelt Hospital, and were all operated upon either by Dr. Hartley or myself.

The length of time occupied in attaining sound healing has varied from one week to two months. Some of the best results have been accomplished on the most extensive surfaces. In regard to the permanency of the grafts, I may say that it is remarkably good. Most of the cases reported have been kept under observation, and in no case has anything more than a very minute breaking down of the new tissue been noted. Of course, no claim is made that Thiersch's grafting will prevent the return of malignant disease, but it is certainly much to be desired that after all operations on malignant disease the wounds should be healed at the earliest possible moment. The application of the method will, I feel sure, become constantly more extensive, and no one who gives it a trial can fail to be convinced of its very great value.

I should like now to present a few cases for your inspection. My house surgeon, Dr. Tousey, has kindly brought them here.

RUPTURE OF THE MEMBRANES TWENTY-FIVE DAYS BEFORE THE BIRTH OF A HEALTHY CHILD.

By P. B. EGAN,

ASSISTANT SURGEON, U.S.A.

The origin and uses of the liquor amnii are matters about which there is little accord. On the one hand it is claimed to be the product of fœtal excretion; on the other, it is said to arise by transudation from the vessels of the parent circulation.

The facts that the amnion is a fœtal membrane, that the fluid therein has been found to contain urea and meconium, and that pathological obstruction of the urethra has produced rupture of the fœtal bladder, are adduced in support of the former theory. The belief, from analogy with the chick and the observations of Mekus, that the fœtus derives his water-supply from the liquor amnii, that that liquor is formed long prior to the period when fœtal excretion begins, and that, finally, its composition is similar to the general composition of the maternal blood, are facts believed to strengthen the second hypothesis.

Neither have the experiments begun by Kuntz and Wiener, and carried on at the present time by Gusserow, Dürssen, Krugenberg, etc., determined whether we should look on the cavity of the amnion as a well-spring or a cesspool. Lusk, following Gusserow, declares that the liquor originally transudes from the fœtal vessels, but is augmented, in the latter months, by fœtal excretions.

More unanimity appears to prevail on the subject of its uses, though all is not harmony even here. These uses are briefly stated by Verrier [1] as follows: "The liquor amnii isolates the various parts of the fœtus, protects them from shock from without, facilitates their movements, prevents their compression, and also that of the cord, and maintains uniform expansion of the ovum." This it does so long as the membranes remain intact. Among obstetrical writers this integrity is considered absolutely essential to the life of the child, and a safe parturition. Cazeaux, in his classical work, declares: "In the latter [labor] they [the waters] seem destined to guard the child from the violence of the uterine contractions, which, without them, would certainly compromise its existence, and to aid in forming the amniotic bag, the engagement of which renders dilatation of the neck more uniform and easy. . . ." Playfair says: "If we evacuate the liquor amnii prematurely, the pressure of the head on the cervix might produce irritation, and seriously prolong the labor." The extreme views on this subject were clearly expressed, in 1885, by Dr. Henry T. Byford, in a paper read before the Chicago Gynecological Society. He described "the possibility, probability, and utility of the preservation of the membranes from rupture, until they dilate, or aid in dilating, the vulvo-vaginal orifice, as well as the cervix." [2]

Numerous cases have, however, shown that this integrity is not essential. The first note of dissent was sounded by Professor Stephenson, of Aberdeen, in the *British Medical Journal* of August 4, 1877. He wrote: "In the face of the fact that much, and often long-continued, ineffectual exertion is frequently due to the integrity of the membranes, even before full dilatation of the os, and the other fact that such ineffectual work is often productive of serious after-complications, there is certainly a want of discussion on this point in our recent works. . . . In reference to puncture of the membranes, I have stated practice is at variance with teaching." He then enumerates four different conditions in which he believes rupture of the membranes, prior to full dilatation of the cervix, to be an advantage.

The most extensive and complete observation on this subject has been furnished by Dr. Kemper, of Indiana. In the *American Journal of the Medical Sciences* for April, 1885, he records fifty cases of spontaneous rupture of the membranes, occurring in seven hundred obstetrical cases. Rupture took place three weeks before the beginning of pains in one case; four days before pains in another; three days before pains in three cases, and two days before pains in one case. As a result of his experience he concludes as follows:

"1. Spontaneous rupture of the membranes at full term of gestation and preceding the beginning of labor pains is an event of common occurrence, averaging about once in fourteen labors.

"3. When such an accident occurs, the duration of labor is not necessarily prolonged or rendered more painful.

"4. The mortality of the mothers is not augmented, and the ratio of still-born children, if at all, is so slightly increased as to amount to a minimum.

"6. It is probable the duration of labor is shorter in cases where the appearance of pains is delayed for some time after the membranes are ruptured.

"8. Finally, that the fear of delay and danger in these cases — the classical 'dry labor' — promulgated by our early obstetrical fathers, and endorsed by successive authors generally, is based on the merest spark of truth, and is one of those medical traditions that experience shows to be overestimated and to a large degree apocryphal."

Space alone prevents more extended quotation from this excellent contribution. It forms, together with those of Eisenhart,[3] the only complete record of extensive modern observation on this subject. Isolated cases with a longer interval between the pains and the onset of labor are sparsely scattered through medical literature. Dr. Anderton reported to the New York Clinical Society a case where labor resulted in the birth of a living child thirty-nine days after rupture of the membranes.[2] Profuse hemorrhage supervened on the ninth day. He also cites the case of Dr. John Gould, in which living twins were born five weeks after the discharge of the waters. Likewise the case of Mr. Thorburn, where, six weeks after the rupture, a healthy child was born. Five other cases, by English observers, are given in which there was a delay of from four to six weeks, but in which, unfortunately, no mention is made of the condition of the child.

As would naturally be supposed, from the eminence of the author, by far the best recorded case is that brought before the London Obstetrical Society by J. Mathews Duncan.[3] Here pregnancy continued for forty-five days after rupture of the membranes. The child was born alive, but died soon afterward. It showed signs of compression. This case will be again frequently alluded to. Charpentier [4] cites the case of Bailly and Garipuy in which thirteen and a half days elapsed. In Chareuil's cases twelve and twenty-seven days intervened. In his own three cases there were intervals of twelve, fourteen, and forty-four days respectively. The two cases of Poullet, in which living children were born five and six weeks after the rupture of the membranes, he considers examples of hydrorrhœa.

The following case is added as a contribution to this comparatively rare and interesting subject:

Mrs. T——, wife of a clerk, thirty-five years old, strongly built and robust. Of good family history and no acquired constitutional defect. Has three living, healthy children—the eldest ten, the youngest six. Since the birth of the latter she has had four miscarriages. The last occurred twelve months ago, when she was in about the seventh month of pregnancy. From an examination of the fœtus the doctor in attendance declared that it had been dead some months.

No cause can be discovered for these "mishaps." Her last monthly sickness occurred about December 20th.

[4] Wood & Co., 1887.

She was taken with labor pains on the evening of August 17th next following. These were succeeded in a few hours by rupture of the membranes, and the escape of a large quantity of liquor amnii. On examination during the evening the os was found to be dilated to the size of a dollar, and the head presenting.

Descent was not yet sufficiently advanced to enable the position of the occiput to be determined. The pains were of the kind known as preparatory or dilating, occurred frequently, and lasted a minute or two. Later in the night the posterior fontanelle was plainly discovered toward the left acetabulum, with the sagittal suture running backward to the right side. As the pains continued to be dilating in character but little advance was made. The patient was assured that everything was progressing favorably, but that delivery would probably not take place before the next day. On the following morning the occiput was no longer within reach. Later in the day it became again discernible. Dilating pains continued at frequent intervals. A small quantity of blood-stained mucus escaped, but no membranes were discoverable. In the evening the patient was given half a grain of morphia in four doses. This produced a night of complete rest. On awakening in the morning she found the pains had vanished. From this time until September 11th the woman attended to the lighter household duties. She suffered from occasional pains, especially during the night. These were situated over the lower part of the abdomen, and were said to be like feeble labor-pains. On the morning of the 11th they became more severe. Examination showed the head presenting as before, in the L. O. A. position. About 10 P.M. the pains became expulsive in character. In one hour a girl was born, weighing six and a quarter pounds. Her body was covered with a large amount of vernix caseosa. Her lips were quite purple, but she immediately began to cry with exceptional vigor, and has since continued healthy. A small quantity of water drained away with the more severe pains, but no membranous bag formed at any time. But one opening could be found in the afterbirth.

The differential diagnosis in this case rests between premature rupture of the membranes and hydrorrhœa gravidarum. The fact that the waters came away in a gush under expanding pains; that it was followed by a bloody, mucous discharge; that it again appeared in small quantity, having probably transuded under the pressure of the severe pains; that "nature's wedge" was absent during delivery; and that, finally, on the first occasion the presentation and position were twice discernible as they have never been to the writer, with the membranes unruptured, led to its diagnosis as above.

The causes which give rise to this condition are variously stated. Eisenhart[1] considers advanced age and pelvic contractures in the woman, and abnormal position and deficient length and weight in the child, as exciting causes. Smellie considered obesity a cause. Verrier[2] considers that "it occurs usually with those presentations where the fœtal part does not hermetically close the lower segment of the womb." Our knowledge on this point is, however, very uncertain.

We are equally in the dark as to why labor does not at once supervene in these cases. Mathews Duncan[3] considers this fact is not to be wondered at in our utter ignorance as to the cause of natural labor. He scouts the hypothesis of Burns, that in these cases the membranes may be again healed. Robert Barnes, in the discussion which followed, suggested that the reason was because the nervous centres had not yet attained the remarkable degree of irritability that characterizes them at full term. Schatz[4] considers there is an inhibitory centre of considerable power, so that the cervix can be dilated by regular pains of pregnancy without being followed by the onset of labor, "because the inhibitory centre energetically antagonizes the irritation proceeding from that part."

Mathews Duncan[1] considers the life of the child is not destroyed in these cases because there is no "active uterine contraction," and it is only such he believes to be able to destroy. Active uterine contractions in the above case lasted but one hour, thus supporting the opinion of Dr. Kemper,[5] that labor is shorter where the membranes have been ruptured a long time prior to its onset.

As labor in the above case was exceptionally easy, the lividity of the child was probably due to the compression to which it had been so long subjected.

Mathews Duncan[3] considers the absence of vernix caseosa in his case as due to the friction from uterine contraction. This observation, however, seems extremely doubtful. Lusk[4] says, the amount of this substance on the body at birth is very variable. Dr. Bartlett[5] reports a case in which the membranes ruptured when the head was on the perineum, and where the vernix caseosa was so thick on the vertex as to give rise to the diagnosis of placenta prævia. "The upper parts of the arms of the child were so bedaubed with the sebaceous secretion as to look like the spokes of a wheel on a muddy road." In one of the writer's cases, where the membranes, containing a large quantity of liquor amnii, ruptured at the proper time, the child was wholly free from vernix caseosa.

FORT DAVIS, TEX.

CONSTIPATION AND SOME OF ITS SEQUELS TREATED BY MEDICO-GYMNASTICS AND MASSAGE.

BY JAKOB BOLIN, M.G.,

NEW YORK.

THE effects of bodily exercise upon the functions of the abdominal organs in health called quite early the attention of the medical profession to the probability of arriving at some beneficial results by treating them by movements and manipulations when in diseased condition. But it seems as if the importance of medico-gymnastics in diseases of the alimentary canal has not been fully appreciated, while massage of the abdomen has become a fad, which threatens more and more to be an intolerable nuisance, for great stress is laid upon this means in a number of diseases where it still remains for the conscientious observer to notice a single case of severe character or long duration which has been carried through to a permanent cure. The prevailing practice, for instance, of prescribing "rubbing" as an excellent means against constipation with slow or deficient peristalsis seems so doubtful, to say the least, that there is danger that this practice alone will tend to degrade massage, a therapeutic agent of greatest value when judiciously employed, to the level of these much-bragged-of panaceas fit for hardly anything more than to bring money into the pockets of the "patentee." It is evident that the largest part of the alimentary canal, being easily accessible to the manipulations of the masseur, must be influenced accordingly. But the question naturally arises whether or not this influence always is for the better, and, if this question be answered in the affirmative, whether it is strong enough to carry the case through to a permanent cure, or necessarily must stop at temporary relief only.

We know and understand easily the value of massage in removing persistent fecal occlusions in the bowels, especially at the cæcum and the sigmoid flexure, even when other means have failed to bring about an evacuation; but removing a lump of fæces is a purely mechanical procedure employed against a symptom only, not against the disease itself, whether this consist of atony of the muscular coats, or in a decreased secretion, or in something else, whatever it may be. Some men, with

[1] Loc. cit. [2] Loc. cit. [3] Loc. cit. [4] Midwifery, 1884.
[5] Journal of the American Medical Association, November 5, 1887.

well-known names as practical masseurs, claim that massage not only pushes the intestinal contents forward toward the rectum and increases the secretion of the parts manipulated, but that it also stimulates the bowels to more active peristaltic movement. For instance, Graham says:[1] "Massage improves the circulation, and pushes along the contents of the accessible portions of the stomach and intestines at the same time, *besides directly stimulating the muscular fibres to contraction*, . . ." with this expression plainly having in mind a peristaltic contraction. To Reibmayr the case seems so clear that it needs no proof beyond the well-known fact of more regular evacuations for the time being, and his somewhat nonchalant assertion that "Die peristaltische Bewegung der Darme wird eine regere."[2]

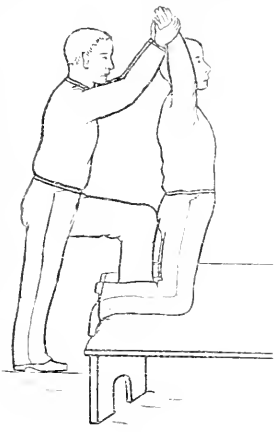

FIG. 1.

A priori we may expect the intestinal musculature to contract under massage just as any other muscle under a mechanical stimulus, which expectation is also proven to be beyond doubt; but the experiments of Nothnagel[3] show us plainly that the contracting effect is exclusively local and cannot be compared with proper peristaltic contractions. And, even if such were the case, it is unreasonable to expect too much of this "exercise" of the involuntary muscles, and to maintain that they thereby regain such vigor as afterward, spontaneously, to perform their work without the normal stimulus of a strong "Bauchpresse," which is just the thing lacking in most cases of constipation, the abdominal walls being weakened by sedentary habits, pregnancy, etc., while the superficial respiration, natural in cases of long standing, at least, makes the movements of the diaphragm much less extensive. And no one claims, I suppose, to be able to increase the respiratory power, or to strengthen the abdominal voluntary muscles to any extent by only "Bauchmassage." For this purpose exercise—movement—is necessary. But exercise is often prescribed without any advice whatsoever being given as to the kind of exercise most suitable for the individual case, and when the question is raised as to the kinds of exercise, walking and horseback-riding are the only ones taken into consideration. Horseback-riding will prove ample in most cases, I think, but for many it is too severe and cannot be endured; while in regard to walking—*i.e.*, the common, everyday, go-easy walking—the direct effect is comparatively small, though it, of course, is of great value as strengthening the whole system.

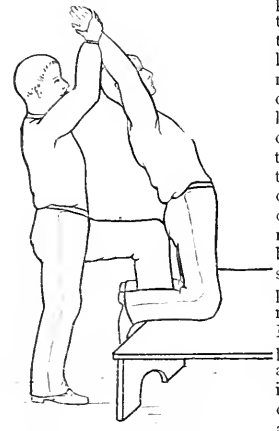

FIG. 2.

When in the following lines recommending a few movements used by medico-gymnasts to the consideration of the practitioner, it is perhaps not out of the way to emphasize that not one of them must be even thought of as a specific, but combined in a certain way they are intended to remove the causes of obstructions, if any there be, to stimulate the respiration, to improve the circulation in general, but especially in the vena-porta system, and to create a strong and healthy "Bauchpresse." The combination of the movements depends, as well as the movements themselves, on the particular needs of the case at hand, and can, of course, not be even touched upon in a short article, so that the programme below is not to be followed as a prescription, but only looked upon as an example to elucidate the general mode of procedure in this method of treating constipation.

FIG. 3.

1. In Fig. 1 the patient is represented as kneeling on a bench, his pelvis fixed by the support of the gymnast's knee on his sacrum, his arms stretched upward and grasped by the gymnast around the wrists, thus by the traction on the pectorals and the expansion of the chest gaining a second support for the abdominal muscles, the two ends of which now are tolerably firm. If the gymnast now execute a slow, steady traction backward, regulating his strength according to that of the patient, who resists as much as he comfortably can do without interfering with the respiration, when he comes to the position denoted in Fig. 2 it is plain that he thereby brings the abdominal muscles into play, not only exercising them, but also by their pressing on the intestines causing them to do part of the work done by his hand in massage, and finally accelerating the circulation in the abdominal tract. The operator brings the patient back to his original position and repeats the movement three to six times with a moment's intermission.

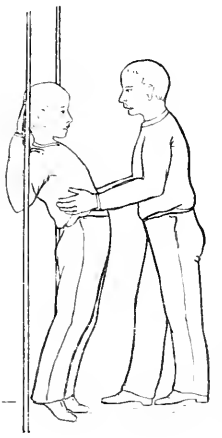

FIG. 4.

If there be very strong relaxation of the abdominal muscles, it will be found more effective to reverse the movement, so that the patient bends backward to the arching position of Fig. 2, and from there rises to the erect position of Fig. 1, under resistance from the gymnast.

2. In Fig. 3 the patient stands between two poles, or in a doorway, with the upper arms horizontally sideward, the forearms and hands stretched upward, resting on the poles. The gymnast stands in front with his hands between the scapulæ. While the patient rises to tiptoes at the moment of inspiration, the gymnast pulls the thoracic walls slightly forward, letting the hands slide along the ribs and executing quick vibrations till the position at the

[1] A Practical Treatise on Massage, etc., p. 124. New York: Wm. Wood & Co. 1884.

[2] Die Massage und ihre Verwerthung, etc., p. 55. Leipzig und Wien, 1886.

[3] Beiträge zur Physiologie und Pathologie des Darmes. Berlin, 1884.

end of the inspiration is as in Fig. 4. During the exhalation the patient sinks down on his heels, while the gymnast relaxes his hold. and brings the hands back to their original place. Repeated five to fifteen times this movement is intended to intensify the respiration, and by so doing not only to increase the movements of the diaphragm but also to decrease the blood-pressure in the extra-pulmonary parts of the thoracic cavity,[1] whereby the venous blood of the abdomen—where the circulation is sluggish—will be, so to say, sucked up toward the heart, relieving the passive stasis of that part. The effect of the vibration is not satisfactorily explained, but it has been empirically noticed to be a valuable help in stimulating the respiration. In a movement of this kind attention should be paid to the necessity of making the respiration powerful and deep, *without special effort, resembling dyspnœic respiration*, which never fails to exhaust the patient.

3. Fig. 5 represents sacral percussion. The patient, standing with support for the arms against the wall, and

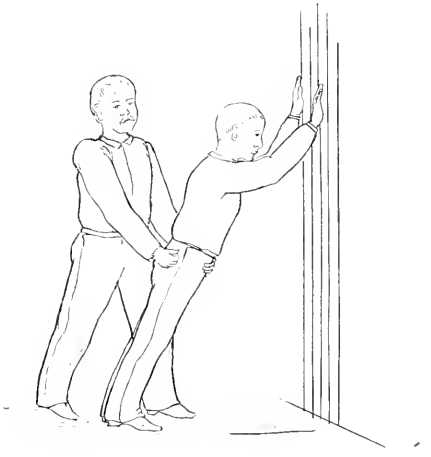

Fig. 5.

the feet a little parted, leans forward, so that the musculature of the abdominal region will be somewhat tense. The gymnast, with one hand supporting the abdomen, executes with his clinched fist quick knocking or percussion over the sacrum during a couple of minutes, with the idea of thereby stimulating the nervous centres supplying the pelvic viscera in general, and more specially acting upon the rectum and the bladder by means of the sacral and pelvic plexuses. This manipulation is by many looked upon as invaluable in severe cases of piles.

The part of the programme now gone through consists of one strong active movement, one very much milder, and one manipulation, and I generally form a programme from such groups of two or three movements, which I have follow each other without any pause, but after which I insist upon at least five minutes' rest, either on the sofa or for stronger patients in walking.

As a second group the following three might be used :

4. The patient lies on the bench, and while his legs are fixed by the gymnast as in Fig. 6, he tries to elevate the body to a sitting position, or rather to an angle of about sixty degrees, from which he again slowly returns to his first position, repeating this three to six times. The lower extremities being fixed as before said, and the thoracic walls by the effort, the abdominal muscles will be called to strong action, more especially perhaps the recti. A moderation of the work performed may of course easily be effected by moving the centre of gravity toward or from the point of attachment of the active force, for instance by letting the patient rest his hands successively on the hips, behind the neck, or keeping them stretched upward in the axis of the trunk.

5. As the second part of this group may very well be applied the "Bauchmassage" proper, for which the patient takes a position in which the muscles are thoroughly relaxed, as in Fig. 7. The procedure of abdominal massage being dwelt upon at length in all handbooks on massage, there is no reason to take time and space for a description here; but it ought perhaps to be remarked that the way of kneading the colon, as generally recommended in manuals, viz., commencing at the cæcum and following the ascending, transvere, and descending parts successively, must certainly not be used in cases of long standing where there are considerable accumulations of hard fecal matters with more or less dilatation. More can be gained by commencing the manipulation as far down in the left iliac fossa as possible, and slowly passing upward to the cæcum. It is evident that the usual way, if employed in these cases, only tends to make things worse, while this latter way offers opportunity to press the hardened substances forward in their natural course.

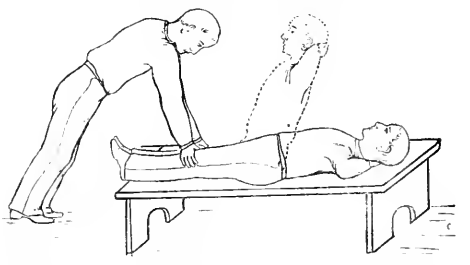

Fig. 6.

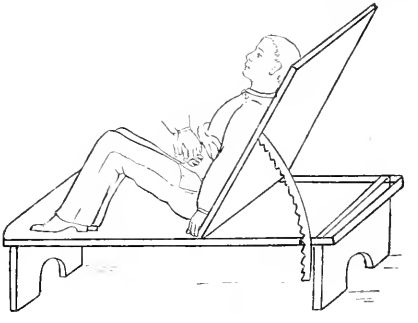

Fig. 7.

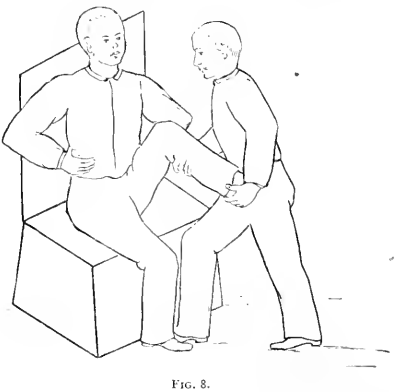

Fig. 8.

[1] Hartelius: Lärobok i sjukgymnastik, p. 205. Stockholm, 1883.

6. Fig. 8 shows the patient sitting in a comfortable position, totally passive, and the gymnast circumducting the thighs alternately outward and inward in large circles six to eight times,-which is repeated in each direction two to five times. If very large circles are used we may expect the movement to have some direct effect on the abdomen on account of the pressure effected at each upward turn, but it is mostly intended to improve the circulation of the lower extremities. The large veins being attached to the fascia, every movement of the hip-joint will alternately increase and decrease the lumen of these vessels, acting consequently as a suction-pump,[1] which of course will be of value for people of sedentary habits with their generally sluggish peripheral circulation.

Here comes in another period of rest.

7. The patient kneels on the bench; the gymnast, standing behind, takes hold under the armpits and allows the patient to fall forward to some extent while giving a pressing support to the patient's pelvis with his knee on the sacrum, and executes thereafter an oscillating movement of the trunk by making alternating sudden tractions on his shoulders. The movement, which though in itself passive, is very tiresome on account of the position, cannot be repeated more than a few times, and must be carefully executed, especially in females. It must never be used in cases of hernia, prolapsus uteri, or uterine displacement.

Fig. 9.

8. After this a respiratory movement is to be recommended in order to regulate the circulation, which perhaps has suffered by the preceding, and "arm-circumduction under toe-heaving" seems to be suitable. The gymnast standing behind the patient makes the circumduction forward, upward, outward, downward, trying to bring the arms as far back as possible in sinking. The patient rises on tiptoes, when the arms are brought forward and upward, and sinks down again when the arms are brought back. Care must be taken to do the movement according to the natural rhythm of respiration, *i.e.*, the arms to be elevated during the inhalation and *vice versa*.

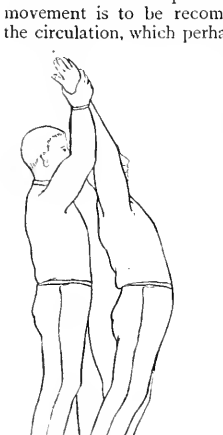

Fig. 10.

These movements, or substitutes for them, for the execution of which about forty-five minutes to an hour are required, will be enough in the majority of cases. For very strong persons several groups may be added, containing different forms of trunk-bending, twistings, and circumductions as active movements, and a great variety of passive movements and manipulations; but we must always bear in mind the golden rule, rather do too little than too much, as nothing is gained by exhausting the patient.

When piles have their origin in constipation they disappear with the cause, and the means employed for the relief of the constipation is, therefore, indirectly, also in piles. When hæmorrhoids are the result of pregnancy or tumors in the pelvis, they probably very seldom, if ever, come under the hands of the masseur or medico gymnast; but when the source is to be found in pulmonary or cardiac diseases, they must, of course, not be overlooked as a symptom of the deranged circulation, and must be healed accordingly. The stagnation in the abdomen must then be relieved by movements (both active and passive as far as the general condition will allow) and massage of the lower extremities, which then also tend to relieve another symptom in these cases—the cold feet. Respiratory movements of many forms are of great value as improving the general circulation, while local massage, consisting mostly of strokings and pressings on and about the piles, are recommended by many, *e.g.*, Hartelius[1] and Nebel.[2]

Most gratifying results are often obtained in cases of prolapsus ani, and I have found the prescription of Brandt to be an excellent one. He gives the patient first the sacrum percussion, already described in connection with constipation, after which he uses his "lifting of the S. romanum," which he describes as follows:[3]

"The position of the patient is the common 'crook-half-lying' (see Fig. 7). The gymnast places himself on the right side of the patient. With his left hand over the shoulder and under the axilla of the patient, he tries, with his right hand on the abdominal wall over the patient's left groin, easily and carefully to push them downward and inward toward the inner side of the os ilium and there with a fine vibration to come under the first curvature of the S. romanum. The movement is then executed toward the back of the patient and toward the gymnast's own left hand. If correctly executed, the patient will plainly notice a pulling in sensation of the rectum. The movement is repeated three to four times."

In addition to these movements of a more local importance, the programme should contain such as will have a strengthening effect on the musculature of the whole lower part, especially the levator ani, besides movements of a more general character.

From what is said above about constipation, it is evident that the treatment recommended for this trouble also must be of value in dilatation of the bowels, as the whole treatment, as laid down above, is based upon efforts to cause the involuntary muscles to contract.

A NEW EXTEMPORANEOUS LITTER, COPIED AFTER THE MOJAVE INDIAN METHOD OF CARRYING THE WOUNDED.

By CHARLES ALBERT SEWALL, M.D.,

ACTING ASSISTANT SURGEON, U.S.A.

While serving at Fort Mojave, A. T., in 1888, I had a wounded Indian, "a Mojave," brought to me for treatment. The patient had his whole arm and forearm shattered by the accidental discharge of a shot-gun; I found it necessary to amputate the limb at the shoulder joint.

The wounded man had been brought over seventeen miles, and his remarkably good condition and the comfortable manner in which the "Indian" Mojaves had taken care of him, called my attention particularly to their peculiar and ingenious method of transportation.

In looking over some of the literature of this subject I have been unable to find anything exactly like it. The materials are always at hand and the contrivance is simple and comfortable, not only to the patient but for the litter-bearers. It is so much easier to carry a load for a distance on the shoulders than by the arms stretched at full length, as they are while carrying the two-handled litter.

[1] Lovén. Blode toch ders Kretslopp, cited by Hartelius, op. cit., p. 207.

[1] Op. cit., p. 277.

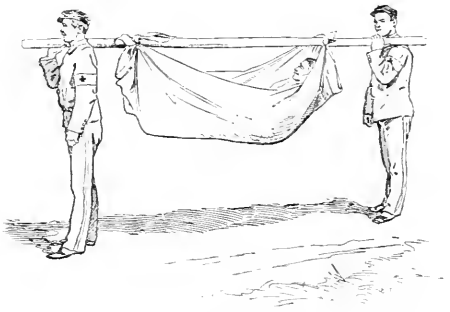
[2] Bewegungskuren mittelst Schwedischer Heilgymnastik und Massage, p. 260. Wiesbaden, 1889.

[3] Gymnastiken såsom bote medel mot qvinliga underlifssjukdomar, p. 163. Stockholm, 1884.

The country in the Colorado River bottom, in Arizona, is exceedingly hot in summer, and at the time of year when the man was wounded the average day and night temperature was 110° F. in the shade.

The comrades of the wounded Indian had exercised much care in his removal over a long, arid, hot river bottom country. They had gotten a wagon sheet of canvas somewhere and a long cottonwood pole; the canvas was loosely tied at the ends, just as one would tie a sling around the neck for a wounded arm, and the pole was slipped under the loosely tied ends, so that when his brother Indians stood erect with the ends of the pole on their shoulders, the canvas bag where the wounded Indian was lying was about from two to four feet from the ground. I tried their palanquin like arrangement by getting in it myself, and found it to be comfortable and pleasant to ride in.

In this instance, where the wounded part was an upper extremity, the slightly flexed position of the body of the patient secured an easy way of riding.



It will be found in Stanley's "Through the Dark Continent," that some of his itineraries were made in a cot or hammock-like arrangement, carried on a pole, but nothing exactly like the above has ever before been shown, to the best of my knowledge.

The materials are as follows: First, a pole, about ten feet long, of sufficient stoutness to carry the weight of a man; the pole may be taken from a fence, or a sapling may be cut for this purpose, and must be moderately smooth, stout, and strong.

Second, a piece of canvas, stout muslin, or an army blanket. This part of the apparatus may be anywhere from 5 × 5 feet, or less, up to 12 × 12; or if it be slightly greater or less in size it does not matter.

In the third place, the cloth, muslin, blanket, or canvas has to be secured to the pole near its ends, leaving just room enough for two men to carry the pole on their shoulders by its extreme ends, and the patient is placed at full length in the bag formed by this sling.

The method of securing the ends of the canvas, cloth, muslin, or blanket, to the ends of the pole, deserves consideration. In the case of canvas the Indians I noticed simply tied a loose "granny" knot at the ends, and slipped the pole under, and when the pole was lifted up by the bearer the bag was formed. This plan I have adopted in all cases where the material is susceptible of being tied and will lie in a flat knot.

It has been suggested to me by Brevet Major-General Eugene A. Carr, U.S.A., that blankets, as an easily available material, would be a fine thing to use for the army in the field, and a device suggested by Major Washington Matthews, Surgeon, U.S.A., by which the blanket is secured to the pole at the ends, I have found to answer most admirably. In each corner of the government blanket, an ordinary gray one, a stone about the size of a lemon is secured by a stout sling or cord, firmly binding it in place, and the corners of the ends of the blanket are fastened together; the pole is then slipped under and when lifted up by the litter-bearers it will be found to be secure and all danger of slipping avoided.

In order to obviate a tendency to slip toward the middle of the pole, which will occasionally be observed, it may be found necessary to drive a small nail on the inside of where the knot or tie comes, or a notch may have to be cut in the pole with a penknife.

The canvas has been found by experience to slip toward the centre much less often than the blanket arrangement.

FORT WINGATE, N. M., July 30, 1890.

Progress of Medical Science.

Recent Views on Diabetes.—The *Lancet* says that diabetes is a disease full of interest, owing in great part to the lacunæ that still exist in our knowledge of its essential nature, and also of the affection standing as a type of disorders in which the processes of nutrition are gravely deranged, and upon which, in consequence, physiological inquiry has an obvious bearing. Dr. Saundby's able exposition of the varied lesions met with post mortem in diabetics, a lecture in which he condensed the results of extended personal observation and study, is especially welcome, since it has dispelled once and for all the notion that morbid anatomy has little to teach on the matter. For, although it must be admitted that many of the lesions he described in the various organs of the body are such as could be adequately referred to the perverted nutritional processes of which the existence of glycosuria is only one indication, it cannot be denied that some of these changes may well stand in quite another relation to the disease itself. Dr. Saundby himself particularized the pancreatic lesions, and the even less constant changes that have been met with in the sympathetic system as having, perhaps, a causal importance. Indeed, there are few subjects more interesting to note than the revival of the notion, advanced by Lancereaux, that disorder of the pancreas can induce diabetes; an opinion fortified by the experimental researches of von Mering and Minkowski, as well as by isolated cases of disease or extirpation of this organ in the human subject. At the same time it would appear that the relationship between pancreatic disease and diabetes is far from being constant. The Bradshawe lecture will be found of value in the incentive it will give to morbid anatomists to utilize their opportunities of making their records of diabates as thorough and complete as possible, by following the lines laid down by the lecturer.

The debate at Berlin served to bring to a common point the wide experience of such eminent authorities as Pavy, Dujardin-Beaumetz, and Seegen upon the all-important question of the treatment of diabetes. Dr. Pavy, who opened the discussion, took the view that diabetes depends on the abnormal entrance into the general circulation of sugar derived from the ingested carbohydrates, rather than on the failure of the organism to destroy the sugar which has already gained entrance. Thus, he pointed out, the liver acts as a kind of storehouse, in which the products of carbohydrate ingestion are arrested normally, but that in diabetes this arrest does not take place, and the sugar entering the general circulation is eliminated by the urine. The phenomena of the disease are thus attributable to the waste of material which should naturally be utilized in the economy, and also to the presence in the blood of an excess of sugar. On these hypotheses he finds the *rationale* of the ordinary dietetic measures which seek to restrict the carbohydrate elements of food; but unless the natural power of assimilation of such material can be restored we cannot be said to cure diabetes. In opium and its derivatives, morphine and codeine, Dr. Pavy thinks we possess remedies which aid in the restoration of this assimilative power. Dr. Dujardin-Beaumetz (whose paper was read in his absence) makes no distinction between glycosuria and diabetes mellitus, for, he remarks, the latter condition itself may be but a symptom of hepatic, pancreatic, or cerebral disease. Prognosis is based on the results of

ness—ventricular or meningeal dropsies being found, and also limited or diffuse sclerosis of the cerebral substance, coinciding closely with thickeningss or thinnings of the adjacent bony walls. Nevertheless it seems right that, when microcephalus exists, an attempt should be made, by removing the resistance of the skull over important centres, to promote the growth of the confined tissues, or at least give them a chance for a new start.

In the *Union Médicale* (Paris), July 8, 1890, Dr. Lannelogue relates that, led by such considerations, he had performed the new operations of "craniectomy" on one patient with what seemed to be pronounced success. The patient, a girl, aged four, of healthy stock and parentage, was born at term, in an apparently healthy condition, and had five healthy brothers and sisters. She was, from birth, more backward than others, and until the third year took only liquid food. Upon examination she was found to be not larger than a feeble child of two years. The saliva escaped from the mouth as in an infant. The eyes were bright and mobile, but her attention could not be held, and she took no interest in what went on around her. She lay constantly in her crib, making frequent inarticulate cries and babbling monosyllables as she moved her body incessantly and aimlessly. She could not stand upon her feet, and when held up and moved forward made no effort to walk, but merely moved the lower limbs up and down rapidly and aimlessly on the same spot. When released she fell all in a heap upon the floor. No contractures nor paralysis could be detected, the general sensibility was normal, the reflexes were not increased, and there was no epileptoid trepidation. The head was small and deformed, the skull being narrow and flattened transversely, bulging at the vertex, after the scaphoid type. The face was prognathous and hatchet-shaped, the nose being large and the forehead receding and very narrow.

Operation having been decided upon, a long and narrow opening was made in the left parietal bone, at the distance of a finger's-breadth from the median line, parallel with the sagittal suture, about nine centimetres long and six millimetres wide. It was very easy to cut this trench through the bone with a stout forceps after a little round opening had been made at one end.

The dura mater was not disturbed. Hemorrhage of the soft parts was at once arrested, and there was practically no loss of blood from the diploe or the meningeal arteries. Care was taken to leave no periosteum in the bony trench, and the surface wound was accurately adjusted without drainage, the line of suture being, as was intended, not directly over the cut in the bone, but to one side of it. Cicatrization occurred rapidly, without suppuration or fever. During the operation a serous liquid exuded in very fine droplets from the surface of the dura mater, and this oozing continued for four or five hours under the first dressing.

The operation was performed on the 9th of May. About the 1st of July her condition was as follows: She has changed greatly for the better since the operation. She is much more calm than before. The almost ceaseless cries which she uttered were discontinued the day after the operation. She now seems to interest herself in what passes around her, playing, laughing, and seeming quite happy when she is noticed. She understands, tries to speak, and pronounces some words. She stands upright by herself without aid, and no longer makes the rapid treading movements. She walks and makes quite regular steps, tottering a little when she hurries, as children do when learning to walk. She does not slaver now. In fine, the phenomena of cerebral excitement, as indicated by incessant cries, and by treading movements of the lower limbs when she is held upright have disappeared. The development of intelligence seems to be making good progress. She can now eat at the table. The cicatrix is mobile and not adherent. At one side of it can be felt a depression, linear and narrow, corresponding to the loss of substance in the bony vault. A part of the good result is doubtless due to the training which the child has received in the wards—which should be always included in the after-treatment of such cases, yet it is evident that the operation may claim a good part of the success.

On June 20th a second patient was operated on, a child of still more marked type of microcephalic idiocy than the former. Two liberating canals were cut, one through the left frontal and the other through the left parietal bone, a bridge being left at the fronto-parietal suture. The results so far were good, the wound healing rapidly.

THE DEADLY CIGARETTE.

It is not very uncommon to see an item in the daily papers to the effect that a boy has killed himself by cigarette smoking. During the past week two cases of this kind were reported. One was that of a boy of fourteen "in whom heart disease had been superinduced by excessive use of cigarettes." In the other case the boy, who was sixteen years old and an inveterate cigarette smoker, hung himself because his father refused to give him money to buy more tobacco.

A year ago Dr. Broomhead reported the case of a boy aged thirteen who died presumably from the results of cigarette smoking. In this case a valvular disease of the heart also was found on autopsy. Since it is not admitted that tobacco can cause organic heart disease, we infer that cigarette smoking is fatal in boys who have organic cardiac or other disease already.

The suicide of the boy cigarette smoker calls attention to the existence of the nicotin psychosis recently described by Kjelberg. It occurs, he thinks, oftener in tobacco-chewers and snuff-takers, but also in smokers. It begins with the symptoms of malaria, insomnia, nervousness and depression, after which hallucinations develop, fixed ideas and a tendency to suicide follow. It is not unlikely that the boy who committed suicide in this city lately was the victim of the nicotin insanity described by Kjelberg.

AMERICAN VERSUS EUROPEAN DIPLOMAS.

The *Medical Press and Circular* makes some sympathetic and kindly comments upon the subject of American medical diplomas. It refers to the discussion upon this subject which took place not long ago in the columns of the Record, and expresses gratification at the tendency toward improvement which American medical colleges are showing. This is an altitude of mind which is but

The country in the Colorado River bottom, in Arizona, is exceedingly hot in summer, and at the time of year when the man was wounded the average day and night temperature was 110° F. in the shade.

The patient, a girl, aged four, of healthy stock and parentage, was born at term, in an apparently healthy condition, and had five healthy brothers and sisters. She was, from birth, more backward than others, and until the third year took only liquid food. Upon examination she was found to be not larger than a feeble child of two years. The saliva escaped from the mouth as in an infant. The eyes were bright and mobile, but her attention could not be held, and she took no interest in what went on around her. She lay constantly in her crib, making frequent inarticulate cries and babbling monosyllables as she moved her body incessantly and aimlessly. She could not stand upon her feet, and when held up and moved forward made no effort to walk, but merely moved the lower limbs up and down rapidly and aimlessly on the same spot. When released she fell all in a heap upon the floor. No contractures nor paralysis could be detected, the general sensibility was normal, the reflexes were not increased, and there was no epileptoid trepidation. The head was small and deformed, the skull being narrow and flattened transversely, bulging at the vertex, after the scaphoid type. The face was prognathous and hatchet-shaped, the nose being large and the forehead receding and very narrow.

Operation having been decided upon, a long and narrow opening was made in the left parietal bone, at the distance of a finger's-breadth from the median line, parallel with the sagittal suture, about nine centimetres long and six millimetres wide. It was very easy to cut this trench through the bone with a stout forceps after a little round opening had been made at one end.

The dura mater was not disturbed. Hemorrhage of the soft parts was at once arrested, and there was practically no loss of blood from the diploe or the meningeal arteries. Care was taken to leave no periosteum in the bony trench, and the surface wound was accurately adjusted without drainage, the line of suture being, as was intended, not directly over the cut in the bone, but to one side of it. Cicatrization occurred rapidly, without suppuration or fever. During the operation a serous liquid exuded in very fine droplets from the surface of the dura mater, and this oozing continued for four or five hours under the first dressing.

The operation was performed on the 9th of May. About the 1st of July her condition was as follows: She has changed greatly for the better since the operation. She is much more calm than before. The almost ceaseless cries which she uttered were discontinued the day after the operation. She now seems to interest herself in what passes around her, playing, laughing, and seeming quite happy when she is noticed. She understands, tries to speak, and pronounces some words. She stands upright by herself without aid, and no longer makes the rapid treading movements. She walks and makes quite regular steps, tottering a little when she hurries, as children do when learning to walk. She does not slaver now. In fine, the phenomena of cerebral excitement, as indicated by incessant cries, and by treading movements of the lower limbs when she is held upright have disappeared. The development of intelligence seems to be making good progress. She can now eat at the table. The cicatrix is mobile and not adherent. At one side of it can be felt a depression, linear and narrow, corresponding to the loss of substance in the bony vault. A part of the good result is doubtless due to the training which the child has received in the wards—which should be always included in the after treatment of such cases, yet it is evident that the operation may claim a good part of the success.

On June 20th a second patient was operated on, a child of still more marked type of microcephalic idiocy than the former. Two liberating canals were cut, one through the left frontal and the other through the left parietal bone, a bridge being left at the fronto-parietal suture. The results so far were good, the wound healing rapidly.

THE DEADLY CIGARETTE.

It is not very uncommon to see an item in the daily papers to the effect that a boy has killed himself by cigarette smoking. During the past week two cases of this kind were reported. One was that of a boy of fourteen "in whom heart disease had been superinduced by excessive use of cigarettes." In the other case the boy, who was sixteen years old and an inveterate cigarette smoker, hung himself because his father refused to give him money to buy more tobacco.

A year ago Dr. Broomhead reported the case of a boy aged thirteen who died presumably from the results of cigarette smoking. In this case a valvular disease of the heart also was found on autopsy. Since it is not admitted that tobacco can cause organic heart disease, we infer that cigarette smoking is fatal in boys who have organic cardiac or other disease already.

The suicide of the boy cigarette smoker calls attention to the existence of the nicotin psychosis recently described by Kjelberg. It occurs, he thinks, oftener in tobacco-chewers and snuff-takers, but also in smokers. It begins with the symptoms of malaria, insomnia, nervousness and depression, after which hallucinations develop, fixed ideas and a tendency to suicide follow. It is not unlikely that the boy who committed suicide in this city lately was the victim of the nicotin insanity described by Kjelberg.

AMERICAN VERSUS EUROPEAN DIPLOMAS.

The *Medical Press and Circular* makes some sympathetic and kindly comments upon the subject of American medical diplomas. It refers to the discussion upon this subject which took place not long ago in the columns of the Record, and expresses gratification at the tendency toward improvement which American medical colleges are showing. This is an altitude of mind which is but

just, yet it is one which our European confreres do not often assume. The number of reputable medical colleges in this country which allow graduation after two courses is rapidly lessening. We believe that after the coming year all the great schools in this city and Philadelphia will make three courses compulsory. With such examples the colleges all over the country that desire to have any standing whatever will have to make a similar advance.

HYPNOTISM AND CRIME.

THE sentence, in Paris, not long ago of a hypnotist to penal servitude for procuring from a somnambulist a check for 10,000 francs, brings home to us, says the *New York Times*, as a practical matter, the possibilities for crime which the facts of hypnotism offer. A writer in the current *Contemporary Review* cites a number of cases which apparently show it to be possible that the greatest crimes may be committed by hypnotists, or at any rate upon hypnotized persons.

The writer in the *Times* adds that it sees no harm in public exhibitions of hypnotism; while the suggestion that an investigation of its phenomena be limited to the medical profession is not satisfactory. For it adds: "The attitude of the profession to the subject has not been historically very satisfactory. They have ridiculed it in the past, and the fear has been expressed that if in the future it should be given over entirely into their hands, they might turn the lock upon investigation. Such a limitation, furthermore, would be extremely difficult to carry out in practice."

Since the *Times* sees no harm in public exhibitions of hypnotism, but does see objections to limiting its investigation to physicians, we would submit to it the reasons for suppressing them, recently set forth by the Russian medical department. It announces that, "In consideration, 1, that public exhibitions of hypnotism cause considerable injury to the health of subjects experimented upon, as well as of spectators witnessing the experiments, the performances being apt to give rise to the development in hypnotized persons of various hysterical, nervous, and even mental affections, which may sometimes amount to a genuine epidemic of hypnotic mania; 2, that such public hypnotic entertainments offer to evil-minded subjects a good opportunity for studying methods of hypnotizing, and for subsequently practising them for various immoral or criminal purposes; 3, that generally such hypnotic performances, being not accompanied by any rational explanation, can breed in the public only erroneous notions, and even implant superstitions, while post-hypnotic suggestions can constitute a source of disturbance of order and the peace of the community by hypnotized persons, and even of committing criminal deeds by the same, the Medical Council has resolved: 1, That henceforward any public *séances* of hypnotism and magnetism are strictly prohibited; and 2, that the application of hypnotism for medical purposes can be permitted solely to medical practitioners, under the condition that the operation is to be practised invariably in the presence of other medical men."

The Garfield Hospital, Washington, D.C., has received a bequest of $10,000.

News of the Week.

The "Grip," which visited us so severely last year, has appeared to a slight extent this Fall. A few cases also have been noted in London.

The Hospital Saturday and Sunday Association held its first meeting for the Fall this week. Among other things they awarded first and second prizes for hymns composed for use on Hospital Sunday.

Paying Practice.—There have been a good many attempts to estimate the average annual income of American physicians, but the variations are so great that no very definite sum can be assumed. Taking only those who have been practising at least ten years, perhaps $1,500 or $2,000 would represent a fair average in the North and West. If a business publication called *The National Medical Exchange* can be credited, however, the country teems with $2,000 and $3,000 practices to be had almost for the asking. Among ninety-three practices for sale nearly all are stated to be worth $2,000, $2,500, or $3,000, a year, while some range much higher. A two thousand dollar homœopathic practice in a town in Ohio is offered for $500 cash. A four thousand dollar practice in New Mexico is offered for $500 cash. Other practices are offered at higher rates.

Dr. Amandus Ferber, a well-known physician of this city, died October 21st, of consumption, at his residence, 79 Second Avenue. He was fifty-eight years of age, and was born in Hamburg.

A Physician Cremated.—The body of Dr. A. B. Carpenter, a prominent physician of Cleveland, O., was incinerated at the Buffalo Crematory, October 21st.

A Well-defined Epidemic of Suicides is at present passing over Europe, in Austria and France, says the *New York Times*. The numbers of self-murders are larger this year than for a long time past. In Germany the annals of daily life in great cities in the past month have been exceptionally full of such records, varied occasionally by horrors such as those recorded lately from Berlin, where a well-to-do head of a family murdered five children in their sleep.

The Cholera.—The epidemic of cholera in Japan is said to be declining in force. Up to the latter part of September there had been 25,723 cases and 16,463 deaths. In Spain there have been 3,658 cases and 1,874 deaths since the epidemic began.

The London Post-Graduate Course.—Six years ago the New York Post-Graduate Medical School was incorporated, and it must be with no little satisfaction and pride that the founders now read of the establishment of the London Post-Graduate Course, with J. Hutchinson, F.R.S., at its head, supported by such men as Dr. J. S. Bristowe, Mr. Reginald Harrison, and Mr. Frederick Treves. Paris now, as well as London, has a school for post graduate instruction; and it is indeed a suggestive fact that these two centres of all former post-graduate learning have felt the necessity of taking the pace set by New York. We send our felicitations to the London school, and wish it a like success to that which the parent school here has had.

The New Jersey State Medical Board.—The first series of examinations to be held under the supervision of the newly-organized State Board of Medical Examiners, in conjunction with the new law, began on Thursday, October 9th, at 9 A. M., in the Senate chamber of the State Capitol at Trenton.

The Kansas Medical College.—The opening exercises of the new Kansas Medical College, at Topeka, were held on the 23d ultimo. Dr. J. C. Minney is the dean.

The Aultman Hospital.—The corner-stone of the new Aultman Hospital, at Canton, O., was laid on the 28th ultimo. The building will contain forty rooms.

Another Swindler.—A shrewd swindler has recently been victimizing the physicians of Columbus, O., by representing that he is a special agent of an insurance company, and appointing them medical examiners of the same. His plan was to call upon a physician, representing himself to be an agent and about to establish a local agency, of which he would appoint the physician upon whom he called a medical examiner. In this manner he victimized several doctors out of sums ranging from $5 to $10.

The Southern Surgical and Gynecological Association.—The next meeting of this association will be held at Atlanta, Ga., on November 11, 12, and 13, 1890.

High Altitudes in Phthisis.—Apart from the extent of the disease, says the *Lancet*, certain constitutional states are contra indications to high altitudes in phthisis. Of these the most important are the rheumatic and gouty conditions, feebleness of the circulation, bronchitis and emphysema, and, lastly, albuminuria. We need have very little hesitation in deciding that no case presenting any of these features can be sent to Davos, St. Moritz, Wiesen, Denver, the Adirondacks, or other high-altitude station, with any reasonable prospect of benefit.

Cœliotomy.—In the interest of correct etymology, appropriate nosology, and the general and eternal fitness of things, Dr. Robert P. Harris wishes surgeons to say "Cœliotomy" instead of "Laparotomy."

Treatment of Chancroids.—At Charity Hospital last week I saw what I consider an improvement in the method of circumcision for chancroids under the prepuce and such ilk. Two lateral flaps are made exposing entirely the glans penis and ulcer. The ulcer is then treated and the flaps are allowed to take pretty much their own course. When the ulcer is healed the flaps are removed and stitches used if necessary. The results are beautiful, and the simple incision which constitutes the primary operation is easily made.—New York Correspondence St. Joseph *Medical Herald.*

Koch's Cure for Consumption.—It will be remembered that Professor Koch created a certain sensation at the International Medical Congress by stating that his unceasing efforts to find a remedy for tuberculosis seemed at last about to be crowned with success. Since then experiments with the new remedy have been going on in Professor Senator's department of the Charité. The time is, of course, much too short for anything like definite results, but as the experiments proceed the veil of secrecy will no doubt be lifted.—Berlin Correspondence *British Medical Journal.*

A Congress of Midwives.—The first Prussian Midwives' Congress was held in Berlin on September 22d and 23d. Six hundred midwives from all parts of Prussia, including the presidents of all the Prussian societies of midwives, were present. Vienna and other parts of Austria were represented. Lectures were delivered, mostly by authorities in obstetrics, and were reported with a view to publication.

Dr. C. Handfield Jones, of London, died at his residence, on September 30th, aged seventy-two years. He was best known by his work on "Functional and Nervous Diseases."

A Medical Monopolist.—The little island of Heligoland is an exceptional bit of territory in many respects, among others in this, that never in the recollection of the "oldest inhabitant" has it been the seat of professional jealousies. Why is it so favored? Because only one medical man (dentist, surgeon, general practitioner, all in one) is to be found the length and breadth of the island. No sooner, however, had Germany taken possession of her new appanage than this delightful state of things seemed destined to come to an end. An announcement appeared in the *Heligoland Gazette*, stating that a second German M.D. would shortly take up his residence in the island. Of course the Heligoland doctor was up in arms at once. He appealed to the new governor, quoting the Emperor William's dictum that the rights and privileges of the Heligolanders were to be respected and to remain unchanged "for the present," and the result is a decree leaving him in undisturbed possession of the sole right of practice in the island.—*British Medical Journal.*

The Leprosy Question is one that will not "down," at least in England. A recent report by the Leprosy Investigation Committee shows an interesting diversity of opinion upon nearly every phase of the subject. Even the contagiousness of leprosy is held in doubt by some experts. Dr. Beaven Rake speaks with scepticism of the immortal case of Father Damien; Dr. Jonathan Hutchinson sticks to his fish-diet theory, and is treated much more kindly by his English confreres *in re* this hypothesis than one would expect; for he only illustrates obstinate adherence to what is utterly untenable. The very slight degree of the contagiousness of leprosy must be admitted by all, and it makes the elaborate attempts at quarantine and isolation of some of the poor victims in this country seem absurd, if not actually barbarous.

The Provincial College of Physicians and Surgeons.—The semi-annual meeting of the Provincial College of Physicians and Surgeons was held recently in the Laval University, Montreal. Thirty-two applicants received their licenses and were sworn in before the Hon. Dr. Ross, President of the Board, last night.

The Rush Hospital.—The charter for the Rush Hospital for Consumption and Allied Diseases having been granted by the Court of Common Pleas, the incorporators have met in the College of Physicians, Thirteenth and Locust streets, Philadelphia, and adopted by-laws for the government of the institution. The object of the hospital, as set forth in the charter, is the treatment and study of consumption and allied diseases, and the improvement of medical knowledge in regard to the same.

Society Reports.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 2, 1890.

ALFRED L. LOOMIS, M.D., PRESIDENT, IN THE CHAIR.

The New Academy Building.—Although the meeting was the first to be held in the new building on West Forty-Third Street, the President stated that a formal dedication would not take place until the anniversary meeting, November 20th.

Skin grafting after the Method of Thiersch. — Dr. Charles McBurney read the paper (see p. 453).

DR. L. A. STIMSON had looked upon Thiersch's method with indifference until he learned of Dr. McBurney's success with it. Since then he had employed it in a number of cases. In old ulcers the result had not been, on the whole, permanent. But he had succeeded with it in covering an epitheliomatous ulcer of the thigh, four by six inches, sparing the patient a hip amputation, which had been suggested by a medical colleague.

Skin-grafting on the Eyelids.—DR. HERMAN KNAPP referred to the case mentioned by the author in which only the outer surface of the cartilage of the eye was affected by an epithelioma. But there were other cases, he said, which were more difficult to manage. For instance, a child fell against a stove, burning the skin over the closed eye; subsequently cicatrices fastened the eyelashes to the eyebrows; the inner surface of the lid became completely everted. The treatment should consist in separating the parts, freshening the raw surfaces, and covering by skin flaps taken from the arm according to Wolf's method, which, he said, was nothing else than a modification of Thiersch's. But he had not thought of following Thiersch's method in these cases as preferable to Wolf's. Operations upon the upper lid had always proven successful in his hands, but not so in the case of the lower lid where tears interfered with union. The grafts should have no subcutaneous tissue if possible. He had been accustomed to stitch them in place. The drawback was the fact that the flaps shrunk greatly.

Hope for Bald Heads.—DR. P. A. MORROW said he had had no personal experience with Thiersch's method. He had used grafts very much thicker than those mentioned in the paper—grafts which included not only the entire thickness of the derma, but also subcutaneous tissue beneath. He had been led to do this in the case of a man who had become somewhat hypochondriac because of a scar on the scalp, which in later years became exposed from scarcity of hair. He first took grafts from the patient's own scalp, on the opposite side, by means of the cutaneous punch, and immediately transplanted them into holes of the same size made by the same instrument in the scar tissue. Very much to his gratification, union was perfect within a week. Four grafts were first made, and he waited several weeks to see whether the hair would grow. It did. He then made transplantations from another patient's scalp, and these also grew and bore hair luxuriantly. The grafts were fully a quarter of an inch thick. There was no suppuration, no untoward result. He had employed the same method in one or two cases of epithelioma, and, while there was no indication of breaking down, there had not been sufficient time to justify conclusions. He thought the method had a wider field of application. For instance, it might be adopted in lupus, and in removing moles, warts, and other facial blemishes.

Grafts from a Negro on a White Man.—DR. JOHN GIRDNER said there was one objection to Thiersch's method, namely, that the new skin was very delicate, and more likely to break down and ulceration return than under the Reverdin method. Where, under the latter method, the islands existed, the skin was deeper and firmer, while the edges were thin and delicate like the Thiersch grafts. He once placed grafts on a white man from a negro; they remained black for a time, but gradually assumed the white appearance of the surrounding skin.

DR. MCBURNEY said, in closing the discussion, that it was evident the different methods mentioned had their special application. In the class of cases referred to by Dr. Knapp, he had operated in a similar manner. He had not practised the method mentioned by Dr. Morrow, but thought it might prove very useful in a special field. But none of the methods named could take the place of Thiersch's in covering a large surface.

CANADIAN MEDICAL ASSOCIATION.

Twenty-Third Annual Meeting, held in the Normal School, Toronto, September 9, 10, and 11, 1890.

JAMES ROSS, M.D., PRESIDENT-ELECT, IN THE CHAIR.

(Special Report by our Canadian Correspondent.)

The President's Address.—He first gave an interesting sketch of the history of the Association since its organization at Quebec, in 1866, and referred to the great progress of medicine since that date. Commenting on the work accomplished by the Association during those years, he paid suitable tribute to those members of the profession by whose enthusiastic labors the Association has been so ably supported. He then briefly reviewed the history of medicine, noting many of the advances which have been made in medical science, and discussed at length many of the questions connected with the profession at the present time. He referred to the great necessity there was for urging the establishment of a uniformity of licenses in the different Provinces of the Dominion of Canada. It was, he felt, a curious fact, that medical men in one Province were not legally qualified to practise their profession in another Province, without first passing the examination prescribed by that Provincial Board. When uniformity in medical licenses was secured between the different Provinces of the Dominion, there might then be some reasonable hope of securing reciprocity in medical registration with Great Britain.

HON. GEO. W. ROSS, Minister of Education for the Province of Ontario, delivered a brief address of welcome. He spoke, in complimentary terms, of the reciprocity of good feeling displayed by the members, and said he had no doubt that, as the President had suggested, it was highly desirable that there should be a uniformity of medical licenses throughout the Dominion, and his influence would be exerted to promote such legislation. After expressing his pleasure in seeing some visitors present from the United States, he concluded by wishing the Association continued prosperity in its work, so that those who have to be the subjects for the doctors' skill will fall under experter hands, and so be enabled to live longer and do good to their fellow-men.

The Address in Medicine was delivered by DR. PREVOST, of Ottawa. The recent advances made in medical science were, he said, probably more marked in bacteriology than in any other department, and by these advances we were now enabled, with no small degree of satisfaction, to study pathogeny, the origin of disease. It is now established that infection is due to the agency of living organisms. Instances were cited of the benefit derived from our knowledge of the germ theory in the study of typhoid, diphtheria, tuberculosis, leprosy, etc. A revolution had thus, in a few years, taken place in the medical world, and in the future much yet remained to be accomplished in discovering the exact agents capable of destroying particular germs. To render the soil inert, brought us to the study of the hygienic surroundings of the patient, and opened a field worthy of the most careful consideration.

MEDICAL SECTION.

Cardiac Complications of Gonorrhœal Rheumatism.—Dr. L. R. MacDonnell, of Montreal, presented a brief *résumé* of the medical literature of the subject, and read notes of twenty-seven cases coming under his observation, in six of which cardiac physical signs were present. In some of these cases there had, however, been a history of scarlet fever or acute rheumatism. Two of the patients had gonorrhœal rheumatism, with distinct heart murmurs, when admitted to the hospital.

Dr. Nesbitt, of Toronto, read a paper on "Pharmacology of Salicylamide."

Spinal Syphilis.—Dr. F. G. Finley, of Montreal, presented a paper on this subject. After referring to the various forms which syphilis may assume in the spinal cord, he related the history of two cases which had recently come under his observation. The symptoms in one case pointed to what was probably a gumma pressing upon the cord, and with the administration of mercury there was rapid improvement. The other case was, he concluded, of the nature of myelitis, and had, as far as he could observe, yielded but slightly to treatment.

Hydatid Tumors.—Dr. H. H. Chown, of Winnipeg, after referring to the origin and formation of these growths from the larval stage to their development in the form of tumors, found sometimes in the liver, peritoneum, brain, lungs, or in the muscles, described the further development of the cyst and its contents. The heads of tænia echinococcus are found, in the various stages of development, and were often sufficiently numerous to render turbid the usually clear fluid contents. These growths gave rise to a variety of symptoms, varying according to the position and size of the tumor. For example, if in the liver we have jaundice, ascites, anasarca, œdema, varicose veins, or paroxysmal pains; if in the lungs, cough, dyspnœa, or hæmoptysis; if in the abdomen, vomiting is a prominent symptom, with pain after each meal. Change was continually going on in these cysts, and either calcareous degeneration, absorption of fluid, or suppuration might occur. Cases are reported where rupture took place into the intestine, the bronchi, bladder, uterus, and into the peritoneal cavity. An exploratory operation was the only means by which a positively correct diagnosis could be made. Microscopical examination of the fluid aided in distinguishing the contents from urine and other fluids. Dr. Chown concluded his interesting paper by describing the different methods of treatment. These were: 1, Electrolysis; 2, puncture and drainage; 3, incision; and 4, excision. The second method was the one most commonly employed, and by it, the contents being expelled, the cyst collapses and absorption is rapidly set up. Success generally followed this method of treatment, which was particularly adapted to tumors of moderate size, and in some of those tumors in the liver, lungs, or spleen. Incision is performed when the tumor is within the peritoneum, with the precautions always observed in such operations. Enucleation became necessary in some cases. The paper concluded with an interesting history of the case of a man, thirty years of age, from whom sixteen separate cysts had been removed from different portions of the abdominal cavity.

The Temperature of the Puerperal Patient was the title of a paper by Dr. Cameron, of Montreal. Careful observation has established the fact that the temperature of the patient is normal at the commencement of labor, and that it rises during the progress of labor, the increase being more marked in primiparæ than in multiparæ. The temperature in every case varies according to the severity and length of the labor. During the first twelve hours after labor there is a rise, and during the next twelve hours there is a fall of temperature. When births occur from 5 A.M. to 2 P.M. the highest temperature is reached; in births from 2 to 6 P.M. the temperature does not rise so high, and in births from 6 P.M. to 4 A.M. the rise is very slight. Thus we note that in births during the night there is little or no rise, and in births during the day the rise is marked. These variations are within the normal range; the proportion of non-febrile cases in midwifery should be about eighty per cent.

Materia Medica.—Dr. W. S. Muir, of Truro, N. S., read the address on this subject. After referring to the importance of the subject, and the importance of medical men being thoroughly acquainted with all the adulterations of drugs, he briefly reviewed the work recently done in the investigation of the action of certain drugs, especially in the groups of antipyretics and heart tonics. He then made reference to some of the newer drugs—exalgine, ural, thyol, ichthyol, thyol-resorciu, and chloralamin. In conclusion he briefly discussed the anæsthetics chloroform, ether, and cocaine, expressing his preference for chloroform as a general anæsthetic, and pointing out some of the serious results that had followed the careless use of cocaine.

Pernicious Anæmia.—Dr. A. McPhedran, of Toronto, presented records of five interesting cases in which there was irregular elevation of temperature; pallor, with the "lemon tint," but without emaciation; high-colored urine of low specific gravity, with the characteristic blood-changes, and gastro-intestinal disturbances. In one case the blood contained 745,000 red corpuscles per cubic millimetre, instead of the normal 5,000,000, the characters of the corpuscles being those typical of the disease. This excessive blood destruction, commencing in the portal system and due to some poison absorbed from the intestinal tract, in which there is probably greatly increased putrefaction going on, was the great characteristic of the disease. In the treatment of these cases he urged the importance of keeping the bowels, as far as possible, clear of decomposing matter, and believed, in addition to an occasional mild calomel purge, the use of an intestinal disinfectant, such as beta naphthol, five grains; or thymol, three grains, three or four times a day, would prove beneficial. In the list of medicines arsenic stands at the head, and should be given in small doses, say one-fortieth of a grain, every two or three hours after food. If not well borne, smaller doses, even a half drop of Fowler's solution, should be tried every hour. The benefit of arsenic was probably by its action on the blood, rendering the hæmoglobin more difficult of being dissolved out of the corpuscles. When, after persevering in its use, it fails, iron should be tried. The diet should be highly nutritious, and consist of iron-bearing foods, as yolk of egg, milk, meat, cereals of all kinds. It was advisable to treat all grave persistent anæmias with arsenic, and by so doing we might possibly prevent some cases of pernicious anæmia.

SURGICAL SECTION.

Peri-urethral Cellulitis.—Sir James Grant, of Ottawa, read a paper on this subject. After pointing out the importance of recognizing the two distinct forms in which this disease is met with, one in isolated patches of small size about the penile portion of the urethra, and the other forming a continuous mass between the layers of the triangular ligament, behind the bulb, he read notes of a case coming under his observation. The patient, a man, aged forty, suffered from extravasation of urine in 1879; he had had a stricture for some years, the sequel to a gonorrhœa. The symptoms becoming urgent, free incisions were made in the perineum, and linseed poultices applied, with great relief to the patient. It was found impossible to pass a catheter. A large portion of the integument of the scrotum sloughed. An opening, three-quarters of an inch in length, into the membranous portion of the urethra, was the result, and urine flowed freely through the perineal fistula. The system was well supported by liberal diet and tonics. The sloughs gradually separated and were replaced by granulation tissue.

The question was, how best to close the fistulous opening? The poultices were continued, the granulation tissue was sufficient to cover the opening and hide it from view. A No. 7 elastic catheter was passed into the urethra, entered slowly through the pouting granulations, and almost unexpectedly reached the bladder, the flow of urine being quite free; it was retained *in situ* and no urine escaped through the fistulous opening. The surface of the granulations was brushed over several times with a weak solution of nitrate of silver. At the end of the third day the catheter was removed, and the urine subsequently flowed only through the natural channel. Healing rapidly occurred in the perineum, and in three months the patient resumed his work. The case served to demonstrate the marvellous reparative power of granulation tissue, even under the most adverse circumstances.

Dr. J. F. W. Ross then read a paper entitled "The Failure of the Removal of the Ovaries and Tubes to Relieve Symptoms."

Cholecystotomy.—Following this, Dr. F. Shepherd, of Montreal, read a paper on "Cholecystotomy." He first gave an interesting sketch of the history of the operation and the difficulties attending it, especially when the gall-bladder was small and shrunken or altered by inflammatory action. The history of a case followed. The patient, a lady, aged fifty-one, had been suffering from pain in the epigastrium and other dyspeptic symptoms for a year, and during that time had lost flesh. After a severe attack of pain in the abdomen, with incessant vomiting, her medical attendant noticed a tumor, about the size of a fœtal head, to the right and a little below the umbilicus, and overlapping the median line. It was freely movable, dull on percussion, very tender, smooth on the surface, but deeper down hard and irregular. There was no history of jaundice or hepatic colic. The growth was considered to be malignant, and probably connected with the bowel. An exploratory incision was determined upon. On coming down to the mass it was found to be an elongated portion of liver, and beneath this was a large, hard mass, covered over by omentum and intestine, and looking like a new growth. In separating this elongated portion of tissue from the mass there was some hemorrhage and an escape of dark-colored fluid. On introducing his finger he felt what proved to be a large gall-stone, and beyond this another, which was extracted with difficulty. The edges of the cavity, which had contained the gall-stones, were so friable that they could not be brought to the abdominal walls, and it was not without some difficulty that a drainage-tube was satisfactorily adjusted and the abdominal wound closed. The patient made an excellent recovery, without any elevation of temperature or increase of pulse. Bile flowed freely from the wound for some days. The tube was removed on the fifth day, and bile ceased to flow on the fifteenth day after the operation. The patient was out, driving, at the end of the second week, and has since been perfectly well. The difficulties in diagnosis of the case, even after the abdomen was opened, were alluded to, and the case was cited as an example of the advantage of exploratory incision in doubtful and even apparently hopeless cases.

Why Apostoli's Method sometimes Fails.—Dr. Lapthorn Smith, of Montreal, after describing the proper way of carrying out the treatment scientifically and efficiently, commented on the causes of failure, the principal one of which was, he thought, the failure to properly apply the positive electrode to the whole uterine surface. To accomplish this he recommended the use of a flexible bougie, and through the use of this he reached every portion of the uterine surface. He related two instances where he had failed on account of the curves in the uterine cavity, but by the use of this elastic bougie every portion of the bleeding surface might be properly brought under the influence of the electrode.

Dr. Holford Walker, of Toronto, read a paper on the same subject, and concluded by expressing his approval of the flexible bougie referred to by Dr. Smith.

Lateral Curvature of the Spine.—Dr. B. E. Mackenzie, of Toronto, presented a case. The patient, a boy, aged five years, had been under treatment for six weeks, and had a marked dorsal curve to the left, with rotation and lumbar curve to the right. The treatment has been mainly directed to develop such muscles as make greatest correction of the deformity. By this means the patient has been enabled, at the present time, by an effort, to straighten the spine, and can hold himself so as to measure three-fourths of an inch more in height than he did six weeks ago. This treatment requires the hearty co-operation of the patient. It is necessary to insist that the best possible attitude be assumed and maintained throughout, and that corrections be made constantly by the surgeon and by the patient when standing before a large mirror. By this means the senses of the patient must be carefully and patiently re-educated. In this case a girdle was employed, secured to a hook, and passing over part of the ribs on the left, made prominent by spinal rotation in the dorsal region. While the patient throws his weight upon the girdle, it is seen that he can over-correct the dorsal curve. At the same time strong pressure is made with the surgeon's hands to press inward and forward the prominent angles of the ribs behind, and inward and backward the part of the ribs of the right side opposite, thus correcting the rotation. During the night the patient uses the usual cradle adopted for such cases. Dr. Mackenzie stated that such treatment was much more satisfactory than by any form of jacket, which caused atrophy of the muscles intended by nature to hold the spine erect, and also greatly restrained the movements of the body. To be successful in this form of treatment it is highly necessary, 1, to give unremitting personal attention to the case for several months; 2, to have the hearty co-operation of the patient—not only the assent, but the positive, determined will; 3, to observe the patient in various attitudes, and to study the effect of the various exercises, so as to strengthen those groups of muscles which are most effective in retaining the best attitude that can be assumed; 4, to combine intelligently the use of a moulding power upon the deformity, such as by the hands of the surgeon, or by Barwell's girdle.

Dr. H. S. Birkett, of Montreal, presented "Notes of a Case of Hemiatrophy of the Tongue," and a paper on "A Method of Preserving Microscopical Specimens of the Eye."

Dr. A. Proudfoot, of Montreal, presented "Notes on a Severe Case of Epilepsy cured by Enucleation of an Eye containing Ossific Deposits."

Dr. H. R. Elliott, of Brucefield, read "A History of a highly Interesting Case of Molluscum Fibrosum," and exhibited the patient, who gave evidence of having all the well-marked symptoms of the disease.

Election of Officers.—The following were unanimously elected for the coming year: *President*, Dr. T. G. Roddick, of Montreal; *General Secretary*, Dr. Birkett, of Montreal; *Treasurer*, Dr. W. H. B. Aikens, of Toronto. *Vice-Presidents:* Ontario, Dr. A. H. Wright, of Toronto; Quebec, Dr. S. P. Lachapell, of Montreal; New Brunswick, Dr. S. H. Coburn, of Fredericton; Nova Scotia, Dr. John Stewart, of Picton; Manitoba, Dr. D. Young, of Selkirk; British Columbia, Dr. E. A. Prayer, of Nanaimo; Prince Edward Island, Dr. Taylor, of Charlottetown; Northwest Territories, Dr. E. A. Kennedy, of Fort McLeod. *Local Secretaries:* Ontario, Dr. Prevost, of Ottawa; Quebec, Dr. P. Robertson, of St. Andrews; New Brunswick, Dr. Bruce, of St. John; Nova Scotia, Dr. A. Morrow, of Halifax; Manitoba, Dr. Milroy, of Portage la Prairie; British Columbia, Dr. Fagan, of New Westminster; Prince Edward Island, Dr. Mackay, of Summerside; Northwest Territories, Dr. Oliver, of Medicine Hat.

Dr. Dillon Brown has been appointed Instructor in Intubation of the Larynx at the New York Polyclinic.

AMERICAN RHINOLOGICAL ASSOCIATION.

Eighth Annual Meeting, Held in Louisville, Ky., October 6, 7, and 8, 1890.

FIRST DAY, MONDAY, OCTOBER 6TH.

Annual Address. — The Association convened at the Galt House, and was called to order by the President, DR. ARTHUR B. HOBBS, of Atlanta, Ga., at 3 P. M., who then delivered the annual address. He said the Association had met to exchange views, to profit by each other's experience and observations, and, not least, to enjoy that social intercourse which fosters a more mutual friendship. This interchange of views raises physicians out of the ruts that they are all liable to fall into during the year of busy practice, and when they return to their consultation-rooms, they will find themselves making additions to their armamentarium. Conservatism should not be too rigidly adhered to in the advancement of science. Mind cannot rub against mind, and experience against experience, without evolving or bringing to light some spark of truth. In order that one may be a successful specialist in any branch it is necessary that he should have had some experience in general practice, and that presupposes that he has studied all the branches; in other words, that his house has been well built in all of its parts before the cupola—his specialty—could have a firm basis. The other parts should not be wholly neglected, because it is through them that the cupola has been reached, and by them it must be supported.

The Relation of Naso-pharyngeal Disease to Catarrh of the Middle Ear.—DR. EMMETT WELSH, of Grand Rapids, Mich., contributed a paper on this subject. He said the relationship existing between naso-pharyngeal disease and catarrh of the middle ear was intimate and inseparable. The ear depended upon a healthy condition of the nares and naso-pharynx for the healthy performance of its function. Patients presenting themselves for the treatment of ear diseases, always give the story of catarrh, located in the nose and throat, and date their primary impairment to this condition; therefore it becomes essential to not only become familiar with the speculum, the rhinoscopic mirror, the catheter, Politzer bag, etc., but also to detect the diseases of the nares and naso-pharynx, its inflammations, obstructive lesions, and measures for their removal.

The existence of a spur upon the septum may be the means of exciting a tinnitus aurium, and how useless direct medication to the ear would be without its removal. It would be erroneous for the rhinologist to ignore the large number of aural complications he meets with in daily practice. This is very apparent, indeed, when we consider that the larger proportion of abnormal changes that take place in the ear, result from those diseases of the naso-pharynx which produce narrowing or obstruction of the Eustachian tube.

Repeated attacks of subacute otitis media can be found in cases directly referable to some mechanical obstruction or inflammatory condition of the naso-pharynx. Its relief is dependent upon this causation, and its treatment plain; yet how often do we find that this is not detected, and the uselessness of direct medication to the ear is patent.

This is best illustrated in cases of children, who, suffering from recurrent attacks of otitis media, are presented for examination and treatment; when on inspection, the membrana tympani is found inflamed, the child suffering from difficulty in breathing, and mouth breathing predominating, the nares inflamed, and an adenomatous growth existing at the vault of the pharynx.

All treatment with a view to correcting the inflammation of the ear is useless, and the only plan is medication of the nares and the naso-pharynx.

Tonsillar Hypertrophy, its Influence on Nasal and Aural Inflammation, with Treatment.—DR. T. H. STUCKY, of Louisville, Ky., read a paper on the above subject. He said of all the diseases of the upper air-passages, he knew of none more conducive to the production of serious after-effects than tonsillar hypertrophy.

As to the etiology, very little is found in current literature. The exanthemata, diphtheria, and frequent attacks of pharyngitis seem to be etiological factors. Sex is not without some influence in producing the affection, for out of one thousand cases recorded by McKenzie, 670 were males, and 327 females. Some cases follow acute attacks of quinsy, hereditary or acquired syphilis, granular pharynx, etc. As a rule, after the age of thirty years, spontaneous cure takes place, it being the natural course of the gland to atrophy after this age.

It is immaterial whether the hypertrophy be due to the engorgement of the crypts or lacunæ due to either an active or passive hyperæmia, or to a true inflammatory hyperplasia, the indications for treatment are cogent. The treatment of the conditions will be variable. Where there is a simple hypertrophy due to an acute catarrhal inflammation, the topical applications of the mild astringents have proven to the author of little benefit.

The rheumatic character of acute tonsillitis or hypertrophy is accepted by a large number of the profession. Salicylate of soda at the commencement of the attack, in ten-grain doses, to an adult, every hour or two until one drachm has been taken, will abort many attacks. On account of the decided nausea produced to many by this drug, Dr. Stucky has used the effervescent salicylate of lithia with equally satisfactory results, with no nausea. For simple acute hypertrophies, the treatment is constitutional and locally astringent. When the tonsils are soft, the galvano-cautery is very effective, a few deep cauterizations being made twice a week. The author has introduced the galvanic needle its full length into the tonsils, at several different points, about one-eighth of an inch distant one from the other, which has proven equally, if not more, efficient than the method mentioned, causing less pain at the time of the operation, and not so much uneasiness afterward in deglutition. The galvano-cautery snare, where there is a history of a hemorrhagic diathesis, is a great addition to the armamentarium of the rhinologist. Dr. Morell Mackenzie recommends the use of London paste, applied once or twice a week, according to circumstances, over various parts of the organ. This method Dr. Stucky considers slow and painful. Where the organ is fibrous, dense, and hard, tonsillectomy should be resorted to. While the danger from hemorrhage is reduced to a minimum, the time, suffering, delays, and inconvenience which are overcome by ablation render it, in his judgment, the operation for speedy relief, and should always be performed where the hypertrophy is dense in character. The tanno-gallic gargle of Mackenzie is an excellent after-treatment for the bleeding. The cold wire snare is painful, slow, and will eventually be superseded by the galvano-cautery. The simpler the after-local treatment is, the better and more speedy the results. The cause being removed, the use of a cleansing spray of melted vaseline, with an astringent, stimulant, or sedative, as required, will rapidly give relief If the uvula and soft palate remain relaxed after tonsillectomy and the use of the astringents, amputate the uvula. The ear symptoms, if acute, generally subside rapidly. After removal, special attention is called to the condition of the nasal passages. If hypertrophies of a chronic character exist over any of the turbinated processes, remove them by cautery, or other means. The simple distention of the Eustachian tube, by the method of Politzer or Valsalva, will oftentimes relieve the patient by a few treatments. These methods should never be used unless the nasal passages as well as the vault of the pharynx have been thoroughly cleansed. If there is no marked change in the tympanum, the method of Delstauch (massage) will prove of service. Of all the methods named, tonsillectomy or ablation, and the galvano cautery, in the author's opinion, are the best.

SECOND DAY, TUESDAY, OCTOBER 7TH.—MORNING SESSION.

The Association was called to order by the President at 10 A.M.

Nasal Cauteries.—DR. E. R. LEWIS, of Indianapolis, Ind., read a paper on this subject. He said London paste or Vienna paste, or caustic paste in any form, he never uses in the treatment of nasal hypertrophies. He has patients under his care who wish that it had never been used on them, and yet it was used by specialists competent to make the best use of it. In the treatment of posterior hypertrophies by means of a guarded porte-caustique, chromic acid can be easily and safely used, and the results be satisfactory in many cases. The general practitioner who is not provided with the apparatus of a specialist, and yet is called upon to treat nasal hypertrophies, will do well to use chromic acid in preference to any other caustic. Nitrate of silver is to be condemned in nasal treatment. In Dr. Lewis' practice the galvano-cautery has taken the place of all other nasal cauteries. It is not a case of prejudice, but a clear case of the survival of the fittest. The galvano-cautery does its work neatly, aseptically, and, when properly used, painlessly and bloodlessly. For all nasal operations, except the removal of large growths by the loop, a small storage battery is the most useful and the most convenient. The small storage-battery he has in his office is kept constantly charged from four cells placed in the cellar beneath. It can be easily detached and taken out of the office and used for days without being recharged. For the loop a larger or double battery is necessary, but even in that case the battery can easily be carried in the hand. He highly recommended the galvano-cautery, and coupled his recommendation with the following cautions:

"1. Adopt preliminary treatment, even if there is not much congestion or hyperæmia. I request, and in some cases demand, to have the patient under my treatment two weeks at least before cauterizing, and in many cases I wish a longer time. The results are always more satisfactory after such preliminary treatment, and the work to be done by the cautery can be better gauged.

"2. Cauterize in the anterior portion first, and use the edge of the knife—not the flat surface—sinking it in as far as seems necessary and drawing it forward. It seems best to keep the knife moving; if stationary for a while it is apt to stick to the tissue. I usually apply the edge of the knife to the inside, pressing it outward and drawing it forward; then, if necessary, the edge to the lower part, pressing it upward and drawing it forward. One electrode may be used for both operations where one is skilled in it, or two electrodes may be used, one horizontal when introduced, and the other perpendicular.

"3. Spray the parts well, but gently, with soothing sprays after the cauterization. I use oil of vaseline with a little eucalyptol in it, then a warmed Seiler's solution, and finally, oil of vaseline again medicated as before. The medicated oil is varied in different cases. Sometimes I use oil medicated with iodol.

"4. Never cauterize on both sides at one sitting. I make no exception to this rule in my own practice.

"5. Introduce the electrode while cold, apply it to the posterior part of the hypertrophy to be cauterized, then press the knob to heat the electrode and begin to draw it forward. The maximum heat has been determined before by the regulation of the rheostat. I prefer a bright red turning to white, and obtain the best results from such heat. In this respect I confess that I do not agree with or understand Lennox Browne (3d edition, 1890, p. 141), unless he refers to the heat required in ear and throat and elsewhere. A black heat I never use; a dull-red heat is apt to make the knife stick; a bright-red heat, even if inclining to white, is, to me, the best. It must be remembered that the electrode is cooled considerably by the secretions and by the body when made to enter it. The thumb should be withdrawn from the knob before withdrawing the electrode, so that it may be withdrawn cold.

"6. The parts should be treated gently and soothingly for several days after cauterization, the secretions being removed and the nares cleansed with as little irritation as possible. If the other side is to be cauterized, a week should be allowed to intervene, if possible, before doing it. I recommend that the anterior part of the hypertrophy be cauterized first. If the hypertrophy is so large that it requires it, the next operation may be begun further back, and so till all is removed at several sittings. Sometimes, after a satisfactory cauterization of the anterior part, the posterior part can be easily removed with the snare, where it would have been very difficult to use the snare on the entire hypertrophy.

"I apply the cocaine by means of cotton on a probe, using a fresh ten per cent. solution. The cotton is gently applied to the anterior part, held in position a few seconds, then gently and slowly pushed back. Care is taken to have the sides and lower part of the hypertrophy well moistened by the solution, although the cotton must not be so saturated that the solution will run into the throat, or drop on the floor of the nares. In a few moments the parts are ready for the cautery. There is absolutely no pain; rarely is there a drop of blood; the after-pain in the great majority of cases is *nil*.

"In a few cases there is slight nausea felt at the close of the application of the cocaine or during or after the use of the cautery. In such cases a little wine or brandy is given, and the disagreeable feeling passes off."

Nasal and Pharyngeal Manifestations of Syphilis; Results and Treatment.—DR. J. G. CARPENTER, of Stanford, Ky., read a paper on this subject. He said primary syphilis, including the period of inoculation, development of the chancre, and infection of the adjacent glands, is found infrequently in the nasal and pharyngeal chambers, though more frequently in the mouth and upon the lips; consequently the secondary form of syphilis and its sequelæ concern the rhinologist more than any other variety. The presence of the initial lesions of syphilis in the nasal or pharyngeal chambers causes swelling of the mucous lining, pain, fever, infection of adjacent glands, and in the nasal chambers difficult nasal respiration.

Syphilitic rhinitis may occur as the result of heredity; the local lesions of secondary syphilis found in the upper air-passages may begin as a catarrhal inflammation—rhinitis or pharyngitis, a local circumscribed erythema, a papular, pustular, or tubercular deposit. The epithelium of the mucous membrane becomes rapidly softened, disintegrated, and abraded, leaving one or several erosions, becoming quite painful, sensitive, and at first bathed in a mucous secretion, which soon becomes muco-purulent or purulent as the ulcers enlarge and disintegrate.

In the treatment of syphilis of the nose and throat it is very important to arrest and cure the disease in the shortest period possible, to prevent destruction of tissue and deformity following syphilitic ulceration of the soft tissues of the nose, palate, pharynx, and larynx, such as dysphagia and faulty voice. The anterior or posterior nares, or Eustachian orifices, may be occluded by adhesions so as to interfere with their function.

The best remedy for the treatment and cure of syphilis is mercury; it produces fatty metamorphosis. The continuous use of mercury in small tonic doses, from one to three years, short of producing tenderness of the gums and slight ptyalism or relaxation of the bowels, is the most appropriate treatment for the permanent cure and eradication of the disease from the system. The proto-iodide, the bichloride, and biniodide of mercury stand at the head of mercurial preparations. External applications to the groins, armpits, inside of the thighs, two or three times daily, are adjuvants of the greatest importance in the treatment of syphilis.

The local treatment of syphilitic lesions of the naso-pharynx and larynx consists in mild antiseptic and aseptic, soothing, cleansing applications, to disinfect, soften, de-

tach, and wash away the morbid secretions and crusts which vitiate the respired air and act as foreign material, causing constant irritation, and the use of such other medicaments as will arrest and restore the affected parts to a normal state, in the shortest period, in conjunction with constitutional measures.

For the treatment of the sequelæ of syphilis, caries and necrosis of bone and cartilage of the contiguous bones of the naso-pharynx and larynx, the same surgical rules hold good as in other localities, viz., to remove the dead bone, prevent further disintegration, and render the wound aseptic

---

AFTERNOON SESSION.

Nasal Hypertrophies.—DR. JOHN NORTH, of Toledo, O., contributed a paper on this subject, in which he said the framework of the nasal fossæ consists of hard, unyielding bone. These bony fossæ are lined with mucous membrane. The abnormal thickening and growth of the mucous membrane of the nasal fossæ is spoken of as nasal hypertrophy. The thickening and growth of this membrane naturally diminishes the normal lumen of the nasal passages, interfering with the free nasal respirations, proper resonance of the voice, and of the functions of the nasal passages, in addition to the reflex contiguous troubles that rhino-laryngologists are called upon to consider and investigate.

The term nasal hypertrophy is frequently applied to all conditions of the nasal mucous membrane in which there is a thickened condition of the membrane and a narrowing of the lumen of the nasal cavities, not dependent upon anatomical abnormalities or tumors.

Dr. North divided them into, 1, chronic hyperæmia; 2, simple hypertrophy; 3, hypertrophy with hyperplasia; 4, hyperplasia; and 5, neoplasia.

1. *Chronic hyperæmia.*—In this condition we have a superabundant supply of blood to the parts, dependent upon some derangement, a paresis, of the vaso-motor nervous system. There is no doubt of the existence of nerves, distributed to the muscular coats of the blood-vessels, which are capable of regulating their calibre and the quantity of blood sent to the different parts. It has been shown, by experiments upon living animals, that local variations in the circulation, independent of the action of the heart, actually take place, and that they are of great importance in their special functions.

2. *Simple hypertrophy* is due to hypernutrition. There is no increase in the relative number of tissue-elements. There is simply over-nutrition and consequent over-growth of existing elements, dependent upon increased supply of nutrient pabulum.

3. *Hypertrophy with hyperplasia* may be due to hypernutrition from hyperæmia, or congestion and inflammation produced by various causes.

4. *Hyperplasia* is caused from hypernutrition, congestion, and inflammation. In nasal hyperplasia there is no growth of the tissue-elements. The increase in the thickness of the membrane occurs from simple hyperplasia, or the organization of the products of inflammation thrown out from the vessels in the stage of congestion and exudation. Atrophy usually follows hyperplasia of nasal mucous membrane. Hyperplasia is sometimes called pseudo-hypertrophy.

5. *Nepolasia* is a new-growth appearing upon the turbinated processes, usually well back; the surfaces are rough and irregular, and are not hypertrophies nor hyperplasias, but are separate and distinct growths.

The methods used to restore the lumen of the nose should be such as are required for the general and local condition. In the case of true hypertrophy, all that can be done by medicated vaseline used with the spray is to cleanse the membrane and protect it from further irritation, and allow nature to relieve the case. Prompt and permanent relief can be obtained by the removal of a small portion of the excessive growth. In these cases Dr. North prefers the chromic anhydride (chromic acid), because it can be applied to a small portion of the membrane; it is circumscribed in its action, and the cicatricial tissue that it produces continues to shrink for a considerable time. He finds the membrane in a better condition several months after the operation than it was at first. A spray of medicated vaseline should be continued during the entire treatment.

In cases of hyperplasia, the local application of iodomized vaseline is of the greatest importance. Neoplastic growths are easily removed by the snare, chromic anhydride, or electro-cautery. Constitutional treatment should never be neglected in any case.

Administration of Morphine by the Nostrils.—DR. CARL H. VON KLEIN, of Dayton, O., read a paper on this subject. He said, in the administration of morphine by the mouth there is generally, besides an unprecipitate taste, a great deal of hacking and spitting, in many instances to such an extent that it produces an irritation of the throat, especially of the soft palate. In persons not accustomed to its use it produces nausea and vomiting. Billroth reports the case of a lady—who took ¼ grain in which he saw such anxiety, nausea, and vomiting that, although suffering intense pain, the patient refused to take the remedy again. Dr. von Klein has administered morphine through the mucous membrane of the nose in over one hundred cases, with very satisfactory results. The manner of administering morphine through the olfactory canal is simply by snuffing it up the nasal chambers in the same manner as snuff tobacco is used. The dose is divided into two equal parts, each part being placed upon the end of the thumb and snuffed up into the nostrils. He has found this mode of administering it the most reliable, as it is tasteless, and the drug is more prompt in its action than when administered either by the mouth or hypodermically.

Nasal Reflexes.—DR. A. B. THRASHER, of Cincinnati, O., in a paper on this subject, said that the multiplicity of symptoms attributed by the modern rhinologist to nasal reflexes has caused not a little opprobrium to fall to the lot of the specialist.

Among the affections attributable to intranasal lesions are: Asthma, hay fever, cough, spasm of glottis, gastralgia, dyspepsia, tumefaction and redness of skin of nose, œdema of conjunctiva, conjunctivitis, photophobia, epiphora, asthenopia, glaucoma, scotoma, salivation, cardiac palpitation, disorders of smell, taste, hearing, and sight, huskiness of voice and aphonia, exophthalmic goitre, rheumatic pains, vertigo, chorea, epilepsy, melancholia, agoraphobia, aprosexia, neurasthenia, migraine, cephalalgia, neuralgias, nocturnal eneuresis, many uterine disorders, affections of the genito-urinary mucous membrane, etc.

Many of the affections are not true reflexes, but are caused by blood-pressure or by extension of inflammation, by continuity of tissue, or in some other way not reflex. The specialist should carefully examine the nose, but he should also be a general physician and search the entire system for the obscure *causa morbi*.

Dr. Thrasher reported two cases of reflex salivation, due to intranasal disease. He thought that the cause of the nasal reflex was twofold. Primarily, a diseased condition of the respiratory tract of the nose; secondarily, an abnormal irritability of the central nervous ganglia. This affection of the central nervous system might be caused by repeated irritation of the intranasal tissues; or it might be due to some extranasal irritation. It was more apt to be manifest in individuals of a nervous dyscrasia. The condition of vaso-motor paresis, very different from active inflammation, is generally present, although it may be masked by acute inflammation. The immediate exciting cause of the reflex may be a mechanical, chemical, or thermal irritant.

There is at times some difficulty in making the diagnosis, as the severity of the reflex is not in proportion to the amount of nasal disease. Neither does it follow that

when one of the above symptoms is present, along with well-marked intranasal disease, that the latter is due to the former. Sometimes the local application of cocaine will abolish the reflex; or, again, it may be excited by the irritation of a nasal probe, but the means are not always to be relied on. As a rule, constitutional as well as local treatment must be instituted. In these reflex disturbances it becomes apparent that the specialist should be broad in his ideas, not viewing the whole world through his nasal speculum, or not expecting to see the cause of all bodily ailments reflected in his rhinoscope.

THIRD DAY, WEDNESDAY, OCTOBER 8TH.

Dr. R. S. Knode, of Omaha, Neb., contributed a paper on "What Shall be our Excipients in Nasal Sprays?" which elicited a spirited discussion.

The subject of "Hay Asthma" came up for general discussion and was opened by Dr. A. De Vilbiss, of Toledo, O.

Officers for 1891. — *President*, Dr. R. S. Knode, of Omaha, Neb.; *First Vice-President*, Dr. T. H. Stucky, of Louisville, Ky.; *Second Vice-President*, Dr. C. F. McGahan, of Chattanooga, Tenn.; *Secretary and Treasurer*, Dr. E. R. Lewis, of Indianapolis, Ind.

The next annual meeting will be held at Indianapolis, Ind., in 1891.

Correspondence.

HYDROPHOBIC EPIDEMIC NO MYTH.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Since there is a manifest disposition in some quarters to underrate and make light of the prevailing epidemic of hydrophobia, and to throw doubt on the existence, even, of such a disease, it is deemed proper to record the following four cases, resulting in death, which have occurred therefrom in Central Missouri during the last nine months, and to submit some general thoughts bearing on the subject. And more especially does this appear necessary because the doubt has found expression in these words: "And where are the cases of hydrophobia, dead or dying, throughout the land?" Now, while four cases do not make an epidemic, no more than one swallow ushers in spring, still, when considered in connection with the wide-spread manifestation of the disease under its true name—rabies canina—it points in that direction, and is calculated to give much solicitude to persons residing in communities where so many animals are affected, even unto death, despite all the precautions which have been taken. Speaking according to the facts, the epidemic applies especially to the lower animals—the dog, cat, horse, cow, hog—and does not strictly include humans; yet many persons are bitten, and every once and awhile one succumbs to the inevitable; besides, the peace, happiness, and lives of the whole community are continually jeopardized by contact with this state of reigning terror, which would be infinitely worse were it not for the great amount of caution observed. These four deaths from hydrophobia occurred within fifty miles of this locality, and there may possibly have been others not heard from.

Two of the cases are recorded from written statements given by the doctors in attendance, and the other two on the declaration of reliable eye-witnesses, besides detailed accounts published at the time in the immediate vicinity.

The first case was that of Manny McMillan, of Marshall, County of Saline, twenty miles from this city. He was twenty years of age, and was bitten through the lip by a dog belonging to Dr. McClory, on October 17, 1889. He was seen in ten minutes after by the doctor, when the wound was cauterized by carbolic acid slightly diluted, and otherwise properly dressed. The doctor states that, five days after, the wound looked well, and gave no trouble except a slight pain in the side of the face.

October 30th he had a chill, went to bed, and attempted to drink some water, which threw him into spasms. These continuing more or less frequently, he became wilder and weaker till death released him on the evening of November 1st following. Dying such a horrible death, in the first blush of young manhood, from one of the seemingly needless causes of death, greatly excited the community in which he resided and was much respected. The dog disappeared from his home the same day and was seen no more. Before leaving, however, he bit a great many dogs in the town. These were all killed immediately. The dog showed all the early symptoms of rabies, but as it was the first case they were not recognized at the time, and were only called to mind after he had bitten the young man and gone on his raging tramp, doubtless to his death. McMillan was frequently at the dog's home, and was in the habit of playing with him; in fact, had just left and gone into the street when the dog jumped the fence and snapped him as he passed. This patient was exposed to damp, cold weather after having been bitten; and this, in connection with the fact that the wound was on the face, where the capillary circulation is very active, may account possibly for the short stage of incubation. Next in order of time is the case of Walter Nicholson, of Lincoln, Benton County, a man fifty years of age, and of influence in his vicinity. On November 10, 1889, while in the street, he was bitten on the finger by a stray dog, which soon gave proof that he was laboring under an attack of rabies. The dog was killed, also other dogs that had been bitten by him. Mr. Nicholson went to a city not very distant on the hunt of a madstone and other relief, all to no purpose, for on Christmas-day following he was attacked with spasms and other symptoms characteristic of hydrophobia, and died a most painful and horrifying death in forty-eight hours. It took six men to hold him in bed. While in his rational moments he requested that everything in the house used by him during his illness should be burned after his death, which was accordingly done. The dog which bit him also bit several hogs that went mad in due time. The next case is that of the little four-year-old son of Edward Davidson, of Slater, Saline County, some twenty-six miles from this point.

Dr. B. F. Wilson of that place, who saw the case, states that on December 24, 1889, Mr. Davidson told his son to catch a stray cat that was on the wood-pile, and when the child was within five feet of the cat it jumped at him, seizing his hand, and the father, who witnessed the act, had to sever the cat's head to release the boy. There is no mention as to whether the child was treated preventively or not, but on the 12th of last April he states the child manifested symptoms of chill, followed by fever, and at night of the same day there was great difficulty in deglutition and preternatural nervous excitability. All these morbid phenomena were intensified the next day, and on the 14th the child expired, the predominant symptoms being rapid pulse, tetanic spasms, and difficult swallowing. A week previous to the chill his parents noticed a want of co-ordination in walking. From the time he was bitten till the 5th of April there was nothing to indicate the working of the deadly poison within his body, which was soon to make itself known in such a terribly agonizing form. This mad cat not only bit, but held on to its death-grip, thus differing essentially from the dog, which snaps and runs away, as a rule. Possibly this may be characteristic of the cat in its madness, for a case was recently published in Virginia of a rabid cat biting and holding on to the person till it was decapitated.

The fourth case is that of Mr. Lloy Wingate, living near Caldwell, Callaway County. May 14, 1889, he was at his barn and saw the mad dog coming. He got his shot-gun, jumped over the lot fence trying to avoid the dog and

shoot him. Wingate, thinking the dog was coming to him, jumped over into the lot again, and starting around the stable met the dog face to face. Both barrels of the gun were snapped at the dog, which jumped at him three times. The first and second time Wingate knocked him down, but missing the third time the dog bit him on the hand. A madstone being applied to the wound stuck for eighty-four hours. Other preventive treatment was also given. His family kept a watch on him and thought he was all right again, but on the twenty-seventh day after the bite he called for a drink of water, which being presented occasioned a spasm forthwith. He died on June 14th, the spasms continuing till death released him, which was only three days after the attack. He suffered intensely. The dog that bit him is known to have been bitten by another dog a good while before.

These cases have been given somewhat in detail, so that their reality and genuineness might not be called in question. Here are four well-marked cases of hydrophobia, resulting in death, in a circumscribed district, in a few months; and they occurred under such circumstances as to leave no doubt whatever about the character of the disease. Many other details of these cases could be mentioned, were it considered necessary. What has happened in this section, it is fair to conclude, is not foreign to many other localities throughout the United States, judging from the frequent reports of the newspaper press. And why not give the secular press credit for truthfulness and correct statement when applying to this common trouble, just as is done when it reports murder, theft, arson, rape, fights, and various casualties? Surely there can be no good reason nor sound discretion in tabooing such reports when applying to rabies, and yet accept them in reference to other matters about which mistakes and exaggerations are occasionally made. All the particulars of hydrophobic cases are generally given with great minuteness, because the public is much interested in knowing such things that it may be on the watch-tower. The cases are published right where they occur, and are known to every body in the vicinity. Dates, names, ages, localities, all surrounding circumstances, together with attending physicians, are always given, which stamps the report of these cases with as much truthfulness as any others. In addition to the four cases resulting in death in this part of the State during the prevalence of this trouble, many persons have been bitten by rabid animals and receiving treatment escaped the disease. They have been bitten in every instance, perhaps, under such circumstances as to leave no doubt that it was the result of rabies in the dog. The appearance of a mad dog is well marked, and is known to most persons, from the many descriptions given from time to time, so that when seen he is usually recognized at once, especially if the community is on the lookout. The behavior of such a dog is radically different from one unaffected by rabies; he generally bites right and left promiscuously, without regard to persons or things, and keeps moving right along. Dogs unaffected do not act this way, as is well known to all persons acquainted with them when in a healthy state. In many of the bitten cases in this county the mischief was done by a stray dog invading the premises, and even the dwelling, biting people or any animal in their way. No dog that is not delirious with madness ever acts that way.

As a further test of the true inwardness of these affected dogs, many dogs bitten by them have been isolated and watched till the dread disease, in the course of from three to six weeks, would make its appearance, presenting all the characteristic features. In various parts of this county and adjacent districts, many animals—horses, cattle, hogs—have been bitten, and generally died when the disease developed, if not killed, as a matter of mercy or to insure security to others, before. Two cows and a calf, when they were delirious, wild, and furious, charging upon everything in their way, were killed in this town.

Thomas Ray, three miles east of this place, lost a fine bull and calf, from having been bitten by a stray mad dog, at one time, and five pigs from the bite of another dog at a different time. This stock was isolated; some of them dying in six weeks and others in eight weeks from bite, all of them furiously mad and affected with spasms. After attack, two or three days would wind them up. In the same neighborhood the rabid dogs bit other dogs, which were watched till the disease fully developed, when they were killed. Peter Aikman, living three miles farther east, lost two steers from rabies; one of them, he told me, tried to bite. Dr. T. A. McClory, of Marshall, informs me that he saw two horses, one cow, and three hogs suffering from rabies in that city, and there were many cases in the county, and several rabid dogs were killed. All these animals were wild and furiously mad, and generally died in spasms. This mention is but a sample of what could be related of the prevalence of rabies in other vicinities. In some parts of Illinois and Indiana dogs and stock seem to have suffered equally severely; Texas and Arkansas also have furnished their quota. Only a day or two since a heart-rending account was given of a man dying an awful death, in the throes of hydrophobia, in Arkansas. Reports coming from all parts of the United States bring information of the prevalence, more or less extensively, of the disease; and it is believed to be unjust, and not in accordance with the facts, to attribute this state of affairs to Pasteur Institute influence. It can be affirmed most confidently that no such influence has exerted itself here; the great majority of those who have suffered never having even so much as heard of a Pasteur treatment. It cannot be doubted that the disease is contagious and is transmitted by inoculation through a wound, and when this takes place the disease will develop in a certain proportion of cases, whether in animals or humans, regardless of Pasteur treatment, influence on the mind, or any other considerations. Animals seem to be more susceptible than man, and of course they are unaffected by any such sentiment. The same is true of well-attested cases of hydrophobia in children too young to know what fear of the disease means.

Now these two considerations ought to remove all doubts, it would seem, from the minds of those who investigate with a view to finding the truth about the existence of a genuine disease known as hydrophobia. Feigned cases of the disease once in a great while no doubt appear in highly nervous and hysterical patients, but they are as different in their symptoms and termination from the genuine as day is from night; and the same holds nearly as good as to tetanus. The solution of the wide prevalence of the disease at the present time may be found in the fact that for twenty-five years it has been on the increase. The writer made mention of this in an essay twelve years ago; and newspaper reports from all points of the compass in this country, for the past ten years, plainly tell the tale. Not only in this, but in other countries, especially France and England, has the disease been more prevalent recently than in former years. In consequence of the many outbreaks of rabies in England all the dogs were ordered to be muzzled last January; and as a result, the number of cases of the disorder reported fell from 81 for last quarter of 1889, to 39 for first quarter of this year, and the decrease still goes on. This shows about how much fear, or the hope of relief from Pasteur treatment, has to do with the prevalence of the disease. Cut off all avenues of inoculation, and nothing more will be heard of hydrophobia, even should there be a Pasteur Institute in every county. And why should such an Institute be a cause of harm, any way? It appears to be the most natural thing in the world that, if a person should have unbounded confidence in such treatment, just in that proportion would his mind rest easier and his tendency to fright and despondency be less. There is certainly no well-authenticated case in which the treatment has ever proved injurious; and it cannot be gainsaid that proof, statistical and of the most reliable kind, has time and again been adduced, going to show that Pasteur treatment in France has been a success, all asser-

tions by enemies of the process, or those not posted, to the contrary, notwithstanding. Success does not, of course, mean that everyone who has been inoculated escaped the deadly inroads of the powerful virus, any more than that inoculation or vaccination against variola gives exemption in every case from that pestilent disease. Indeed, some people are so susceptible to small-pox virus that they have repeated attacks. One case was reported from Canada, a few years since, wherein the patient died of the fourth attack, and another was reported from Maryland dying in the third attack.

These being facts, why should infallibly good results be expected in every case to follow anti-rabic treatment? This treatment, too, it must not be forgotten, always follows inoculation of a rabid animal. Doubtless were it applied beforehand, the certainty and efficiency of its operation would be greatly enhanced, as sufficient time would then have been given in which to protect the system. It may be asked in all seriousness whether Pasteur has not long since demonstrated, to the satisfaction of all reasonable people who have grappled with the facts, that the usefulness of his anti-rabic inoculation is placed beyond peradventure? whether, indeed, a proposition could be more thoroughly established than he has done in showing that the system, when once under the influence to saturation of his anti-rabic virus, is proof against all rabid influences whatsoever?

Let those who are disposed to pour cold water on the Pasteur treatment, and always speak deprecatingly of it, if they would know the bed-rock facts, go back to the time of his experimentation on animals—from 1880 to 1884 inclusive.

During this time various experiments were tried; among others was the experiment with two dogs which had been inoculated with rabic virus. One of these dogs was inoculated several times with his modified virus graduated to suit the case, and this dog so treated was wholly unaffected by the deadly virus in his system; while the other dog, being isolated and not subjected to treatment, soon died of rabies. Different repetitions of this experiment ended the same way.

Having been thus greatly encouraged in his efforts at finding a protective vaccine, about the middle of May, 1884, he submitted the result of his tireless work to the Academy of Sciences of Paris, and asked that a commission be appointed before whom he would give a series of experiments bearing on the question. The commission was appointed, consisting of Dr. Béclard, M. Paul Bert, M. Bouley, Dr. Villemin, Dr. Vulpian, and M. Tisserand. These were all learned men, eminently scientific, and held the leading offices in that distinguished body. The practical test of protection was made with fifty-seven dogs. Nineteen of these dogs had previously been submitted to inoculation with his attenuated virus, nineteen had undergone no protective treatment, and nineteen other dogs were rabid. All of them were confined in an inclosure, and the rabid animals put in their deadly work thoroughly and most impartially, with the result of everyone of the unprotected dogs dying in due time with rabies; while those that had been protected were wholly unaffected by the bites of the rabid dogs. This was in the presence and under the supervision of the commission, and in their report they expressed themselves as being entirely satisfied. And in the name of sound reason and common-sense why should it not satisfy everybody?

Many other experiments were tried before this learned and impartial commission, at some of which they took a hand, all going to prove that Pasteur was on the right track; that, in fact, he had discovered a genuine protective against rabies in dogs; and this being admitted, it followed very naturally that the same protective influence could be claimed for man, in strict accordance with all scientific reasoning on the transmissibility of contagious diseases between man and animals. If it afforded prosection in animals, it was bound necessarily to give protection in man, provided the proper degree of attenuation should be obtained to meet his susceptibilities. Not until after he had satisfied himself of the preservative power of his modified virus, and its innocuousness, if properly handled, and had been endorsed by this commission and other eminent scientists, did he venture to use it on the human subject, although frequently opportuned to do so by those who had received wounds from rabid animals. This was a wise caution, and showed a disposition to be on the safe side in the use of a dangerous and untried remedy; and even then it was not tried on anyone who had not been bitten by a mad dog, and, of course, the chances desperate. The same holds good to-day. Unless hydrophobia becomes far more prevalent than at present, the attenuated virus is never likely to be used preventively, as cow-pox virus is against small-pox. Since rabies appears to originate almost exclusively with the dog, a proper and legitimate use of the virus would be to inoculate with it every dog in the land. By government enactment this could be readily done; and it would most effectually put an end to the hydrophobia scare, as well as the disease itself; but, at the same time, an increased impetus would be given to the establishment of Pasteur Institutes for that purpose, and no other, as man would no longer have occasion to use them.

In view of the great danger that would be shunned, and the immense amount of good done, would it not be well to agitate this phase of the question until it is brought to the notice of our legislators? As evidence of failure in the Pasteur treatment, the statement is made, on the authority of Professor Michel Peter, that thirty-seven deaths are officially reported from hydrophobia in the Department of the Seine for the past four years, while during the four years previous only thirty-eight deaths were reported, although Pasteurism was not then in vogue. This is thought to be a clincher—a very deadener in fact; but is it really so? It is believed there is an escape from this seeming clincher, and it is found in the fact of the wide prevalence of the disease nearly all over the civilized world during the past few months. The Pasteur treatment is no more accountable for this than it is for the occasional epidemic tendency of small-pox, influenza, or the greater influx some years than others of house-flies and other insects. It is a matter of fact, however unexplainable with our present knowledge, that some peculiar condition of the atmosphere, or something else, favors such a state of things some years more than others. As the disease has been on the increase for a number of years, an epidemic outbreak might have been naturally expected. No trouble, to anything like the same extent, has ever before occurred in this community; and it can be truthfully stated, without fear of contradiction, that the Pasteur influence has had nothing whatever to do in the matter. Again, the friend of the treatment—Dr. Dujardin-Beaumetz—is quoted as having lost confidence because in the death of six persons from the disease in Paris, in 1889, three of them had been treated protectively, and the other three had received no treatment, yet both parties died just the same. This is no legitimate argument, at least it is not conclusive by any means. Those who received protective vaccination may have deferred it too late; or possibly these patients may have been so susceptible as to have required several applications of the virus, just as is found necessary in about half the cases vaccinated against small-pox. The language attributed to him does not show a loss of confidence, but only that he was in favor of invoking additional measures of safety to meet just such cases.

The question recently asked, "How can you prove that a thing which at best very rarely happens is prevented happening at all by the use of a supposed preventive," is answered most effectively, and to leave no room for doubt, by Pasteur's experiment with the fifty-seven dogs, besides many other experiments, as well as what is witnessed with our own eyes in an epidemic of rabies such as exists at present. These experiments show beyond question that it is prevented from happening in

the lower animals; and the same rule holds good when applied to humans. The Pasteur treatment is nothing more than the removal of the susceptibility in a person to various contagious diseases by inoculating such person with attenuated virus peculiar to these diseases; it matters not whether this attenuation is brought about by its previous passage through the body of an animal not much susceptible, or whether it is effected by some other of the plans now in vogue. The principle is the same, and will hold equally good with all, when the processes to meet each requirement shall have been fully understood. Use of attenuated small-pox virus explains quite satisfactorily this whole business of inoculation against contagious diseases of any and every kind. First, a small portion of the genuine wild virus was inserted beneath the skin. This was attenuation because of its infinitesimal quantity, as compared with that received in the ordinary way. A mild disease was thus produced, with scarcely a death, under preparatory treatment. Surely this was a great improvement; but when Jenner applied the same virus, after having been attenuated by passing through the cow, all that could be desired to meet the case was found. Yet persons there are, in this and other countries, foolish enough to cry it down by every means possible, in the face of a hundred years of success, such as has attended no other remedy; and the recent declaration from Holland, which states that during the years 1870–73, 20,575 persons died of small-pox, and since then, as a result of the strict enforcement of the new vaccination laws, the prevalence of the disease has steadily declined, there having been but a single death reported for last year in the whole kingdom. When serious thought is taken of this fact—when there is a realizing sense that a hundred thousand lives and more have been saved to this little territory in the few years passed since that great mortality—is there not occasion for rejoicing that a better day has dawned; that we live in an age of progress; and cannot a modicum of praise, in strict justice and fairness, be meted out to the noble men who have blazed the way for others to follow?

The reduction from 20,575 deaths in Holland, for three years, to one death for last year, answers the question again, most fully and satisfactorily, "How shall we know whether people are protected or not by these inoculations?" Hydrophobia is rare because such publicity being given to the disease through the newspapers, every community is wide awake and ready to slay all rabid animals immediately as soon as discovered. Hence, instead of doing harm, the advertisement by the press may possibly do a good that is incalculable in its results. The scare about the disease is natural, and just as it should be perhaps, for it wakes up everyone to a realization of a great danger, one in which death is almost a certain portion should the virus be allowed to incubate after a bite, and it does good therefore by inciting to extra precautions.

Because hydrophobia, in consequence of great precautionary measures enforced, has heretofore been rarely seen, is no more reason for doubting its existence than for calling in question the existence of yellow fever, cholera, or leprosy, because those diseases have not been seen by many doctors in the practice of a lifetime.

The foregoing thoughts are not offered as a defence of Pasteurism, but find expression only in the interest of science, justice, and fair-dealing.

B. F. HART, M.D.

SWEET SPRINGS, Mo., September 23, 1890.

FOOT-AND-MOUTH DISEASE AND SCARLATINA:

A REPLY TO PROFESSOR JAMES LAW'S "CORRECTION."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the MEDICAL RECORD of September 13, 1890, Professor Law is quoted as having said, in criticising my paper on Foot-and-Mouth Disease as it affects animals and man, and its relation to human scarlatina as a prophylactic, that "epizootic foot-and-mouth disease had at times attacked nearly all the cattle and the people of Great Britain."

I am very glad he has called attention to that statement, because it needs correction, but not such treatment as Professor Law has given it, or such correction as he has chosen to make. I grant that the words "Great Britain" are not given in their exact phraseological order or connection. This mistake I regret, for it makes his assertion less preposterous than it really is. In order that I may not again be misunderstood, and that "the truth, the whole truth, and nothing but the truth" may be made manifest in relation to this matter, I shall here give Professor Law's entire discussion of my paper, as it may be found in the MEDICAL RECORD of December 10, 1887, pp. 745 and 746, asking Professor Law, and whoever may read these words, to remember the fact that his (Professor Law's) remarks, and those of the gentlemen who participated in the discussion, were supposed to have been faithfully and accurately recorded, *verbatim*, by a trustworthy reporter, who was present at the Academy of Medicine on the evening of December 1, 1887, when my paper was read and discussed, and along with this another fact, namely, that if the report of Professor Law's remarks is untrue and unreliable, then the entire report of the discussion is to be put aside as valueless, or, at least, to be regarded as incorrect and unworthy of confidence. The reporter attributes to Professor Law the following words: "Professor Law was quite sceptical concerning the prophylactic influence of the foot-and-mouth disease, of which he had seen a great deal in Europe, against scarlatina. Epizootic foot-and-mouth disease had at times attacked nearly all the cattle and the people, and considering the fact that the disease was so frequently prevalent, there should be less scarlet fever in Great Britain than in America, where the foot-and-mouth disease was comparatively unknown. But so far as he knew scarlet fever prevailed and was rather fatal in Great Britain, ninety thousand dying of the disease in five years, which did not speak loudly for prophylaxis. Again, the fact that the foot-and-mouth disease conferred so short-lived protection in cattle seemed to argue against the theory that it could protect the human species against scarlet fever. Whole herds of cattle had been attacked the second time within six months after the first attack, showing that it was not merely isolated cases in which the second attack occurred. It was, perhaps, the most contagious malady known, yet the poisonous element did not extend very far into the atmosphere. So if there was no direct contact the probability was that it would not be conveyed from one to another, and in that, he thought, the disease differed from scarlet fever. His personal experience, also, tended in the direction of scepticism. For he had been exposed again and again to the foot-and-mouth disease and had never contracted it, while the very first time he was exposed to scarlet fever he took the disease. It would seem, therefore, that he was susceptible to the one and insusceptible to the other. He was the only member of a family of five which was exposed in that way that took the scarlet fever, which would seem to militate against the idea that one disease acts as a protective against the other.

As to experimentation with the foot-and-mouth disease, he believed that it should be done on the other side of the Atlantic. There were fifteen hundred million dollars worth of cattle in the United States, and there would be a terrible hue and cry should experimentation with the foot-and-mouth disease be carried on here. With regard to prophylaxis of scarlet fever proper, supposing that it could done, might it not be the means of spreading that disease? He feared that Pasteur, great and good as had been his work, had contributed to the spread of anthrax by sending broadcast attenuated virus. For the attenuated virus could be rendered potent and dangerous, and, therefore, a word of caution with regard

to the cultivation of the virus of the foot-and-mouth disease might be proper."

In reply to Dr. J. C. Peters, who spoke with reference to the occurrence of scarlet fever in cattle and horses, Professor Law said: "Dr. Peters's statement should be qualified in this way. Williams and others wrote of scarlet fevers in cattle and horses, because the name, unfortunately, had been given to the disease, but they recognized it as a non-contagious affection, and not identical with that occurring in man. There was no evidence that it was communicable from horse to horse, much less from animals to man."

Those are all the remarks Professor Law made concerning my paper on the evening of December 1, 1887, and unless the reporter was incorrect, those remarks are, word for word, letter for letter, just what Professor Law uttered in the presence and hearing of the New York Academy of Medicine three years ago.

But what does Professor Law claim in his letter, which is to be found in the MEDICAL RECORD of October 4, 1890, pp. 394, 395, and 396?

He first claims that the statement "foot-and-mouth disease had at times attacked nearly all the people of Great Britain" (attributed to him) "is a statement so preposterous that no one at all conversant with the facts could possibly have made it, and most certainly I never did." He also says the statement is so entirely at variance with the truth that he must crave the privilege of correcting it. Will Professor Law just look at the first few lines of his discussion as it is here given (copied from the MEDICAL RECORD, December 10, 1887)? He will find these words: "Professor Law was quite sceptical concerning the prophylactic influence of the foot-and-mouth disease, of which he had seen a great deal in Europe, against scarlet fever. Epizootic foot-and-mouth disease had at times attacked nearly all the cattle and people, and considering the fact that the disease was so frequently prevalent, there should be less scarlet fever in Great Britain," etc. Is the statement he complains of at variance with this one? I think he will discover that his original and accurately reported assertion was indeed preposterous. When, after having said he had seen a great deal of foot-and-mouth disease in Europe, he asserts that epizootic foot and-mouth disease had at times attacked nearly all the cattle and the people, and when, later, he asserts there should be less scarlet fever in Great Britain, etc., what does he, what did he, mean, if not that Europe and Great Britain were the countries where nearly all the cattle and the people had this disease?

Professor Law then, at some length (see MEDICAL RECORD, October 4, 1890), states what he claims to have said while discussing my paper, on December 1, 1887; and as my veracity is attacked, I shall ask Professor Law to compare what he has recently written (which I shall quote just here) with what he actually said three years ago, and then ask him and the profession to determine whether the two coincide. Professor Law says (in above issue of MEDICAL RECORD, p. 394): "Among other things I said that throughout Great Britain farmers were in the habit of purchasing their stock for winter feeding at large fairs or markets, and that as foot-and-mouth disease was perhaps the most contagious of all diseases of ruminants, the droves brought from such markets in certain years had, as a rule, brought the disease with them and contaminated the home stock. In such cases all who took the milk of the infected cows on such farms were exposed to the infection. Similarly, at that date in Great Britain the city dairies were replenished at frequent intervals with cows drawn from the public markets, and already in fine condition, and these were turned over to the butcher in from two to six weeks if they contracted *lung-plague*, or in six to nine months when the yield of milk began to shrink, if they escaped that disease. Thus the city dairies, being all the time restocked from the public market, were all the time exposed to contract foot-and-mouth disease, and, as a matter of fact, those cows that had passed through the limited period of acquired immunity did really contract the affection. By this means the city population were very frequently exposed to the infection, and if the diseases were identical, all persons who had not already suffered from scarlatina should have contracted the malady." He then goes on to say: "This you will perceive is a widely different claim from that so erroneously attributed to me by Dr. Stickler. He makes me say that nearly the whole British nation had suffered from foot-and-mouth disease. What I did say was that they had been exposed to the infection, and would have suffered, if the claim of identity of the two diseases set up by Dr. Stickler had had a basis of truth." I challenge Professor Law, or anyone else, to find a single sentence of the above, as here stated, in his original discussion, and as what he claims to have said is wholly at variance with what he actually did say, his "correction," so far as it aims at stigmatizing me with untruthfulness, I do not accept, neither do I think the profession will justify him in his action. If he did not mean what he said, that was a matter which ought to have been explained at the time. What I aim at is truthfulness and painstaking in my effort to discover whether the disease in question may furnish a means of preventing the development of scarlatina by giving us a virus which will be innocuous and reliable. As yet I claim nothing; I am simply studying and investigating, and as I have opportunity I shall speak and write of what I learn, whether it be encouraging or discouraging. Honest and fair criticism I welcome. Unfair and untrue comment I despise. What I say in this reply to Professor Law, I say in a spirit of kindliness, wishing only to vindicate the position I have taken with reference to this matter.

Respectfully,

JOSEPH WILLIAM STICKLER, M.D.

DERMATOLOGICAL INSTRUCTION IN AMERICA.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: Your editorial of last week, quoting from Dr. Morrow's address on "Dermatological Instruction in America," states the following: "There is no medical school in this country in which the study of diseases of the skin is obligatory; in none is a knowledge of this important branch of medicine required as a condition of graduation; the professor in this department is not allowed to interrogate students, and has no voice in deciding upon their qualifications for a degree."

Will you permit me to say that this is not strictly true? In the College of Physicians and Surgeons of this city the study of diseases of the skin is obligatory. No student is allowed to graduate there without passing an examination in this important branch, while the professor in this department is not only allowed but required to conduct this examination, the result of which decides, in a measure, the student's qualifications for a degree.

I have the honor to be,

Very truly yours,

GEORGE HENRY FOX, M.D.

NEW YORK, October 11, 1890.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 12 to October 18, 1890.

EBERT, RUDOLPH G., Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from duty at Angel Island, Cal., to take effect upon the arrival at that post of Major William H. Gardner, Surgeon, and will then proceed to Vancouver Barracks, Wash., and report to the commanding officer of that post for duty. S. O. 232, par. 15, A. G. O., Washington, D. C., October 3, 1890.

SMITH, ALLEN M., First Lieutenant and Assistant Surgeon. By direction of the Secretary of War, relieved from duty at Fort Snelling, Minn., and will report in person to the commanding officer at Fort Assiniboine, Mont., for duty at that station, relieving Lieutenant Paul Shillock, Assistant Surgeon. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

SHILLOCK, PAUL, Lieutenant and Assistant Surgeon. By direction of the Secretary of War, upon being relieved, will report in person to the commanding officer at Fort Custer, Mont., for duty at that station, relieving Captain William R. Hall, Assistant Surgeon. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

HALL, WILLIAM R., Captain and Assistant Surgeon. By direction of the Secretary of War, upon being relieved, by Lieutenant Shillock, will report in person to the commanding officer at Fort Schuyler, N. Y., for duty at that station, relieving Captain Norton Strong, Assistant Surgeon. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

STRONG, NORTON, Captain and Assistant Surgeon. By direction of the Secretary of War, on being relieved by Captain Hall, will report in person to the commanding officer at Fort Meade, S. Dak., for duty at that station. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

HUBBARD, VAN BUREN, Major and Surgeon. By direction of the Secretary of War, relieved from duty at Columbus Barracks, O., and will report in person to the commanding officer at Fort Spokane, Wash., for duty at that station, relieving Captain Henry S. Turrill, Assistant Surgeon. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

TURRILL, HENRY S., Captain and Assistant Surgeon. By direction of the Secretary of War, on being relieved by Major Hubbard, will report in person to the commanding officer at Madison Barracks, N. Y., for duty at that station, relieving Major John D. Hall, Surgeon. S. O. 232, A. G. O., Washington, D. C., October 3, 1890.

HALL, JOHN D., Major and Surgeon. By direction of the Secretary of War, on being relieved by Captain Turrill, will report in person to the commanding officer at Fort Canby, Wash., for duty at that station. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

STERNBERG, GEORGE M., Major and Surgeon. By direction of the Secretary of War, relieved from duty as Attending Surgeon and Examiner of Recruits at Baltimore, Md., and as a member of the Army Medical Board appointed to meet in New York City, and will repair to San Francisco, Cal., and take charge of the Medical Purveying Depot at that place, as Acting Assistant Medical Purveyor, relieving Colonel B. J. D. Irwin, Surgeon. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

IRWIN, B. J. D., Colonel and Surgeon. By direction of the Secretary of War, on being relieved, will report in person to the commanding general Department of the Columbia, for assignment to duty as Medical Director of that Department, and as Post Surgeon, Vancouver Barracks, Wash., relieving Major William E. Waters, Surgeon, now post surgeon, and temporarily in charge of the Medical Director's office. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

WATERS, WILLIAM E., Major and Surgeon. By direction of the Secretary of War, on being relieved, will report in person to the commanding officer at Fort Custer, Mont., for duty at that station. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

MUNN, CURTIS E., Major and Surgeon. By direction of the Secretary of War, relieved from duty at Angel Island, Cal., and will report in person to the commanding officer at Fort Monroe, Va., for duty at that station, relieving Major John Brooke, Surgeon. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

BROOKE, JOHN, Major and Surgeon. By direction of the Secretary of War, on being relieved by Major Munn, will report in person to the commanding officer at Fort Leavenworth, Kan., for duty at that station, relieving Major Alfred A. Woodhull, Surgeon. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

WOODHULL, ALFRED A., Major and Surgeon. By direction of the Secretary of War, on being relieved by Major Brooke, will report in person to the commanding officer at Fort Sherman, Idaho, for duty at that station. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

BORDEN, WILLIAM C., Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from duty at Fort Sam Houston, Tex., upon the arrival of Lieutenant-Colonel C. C. Byrne, Surgeon, and will report in person to the commanding officer at Fort Davis, Tex., for duty at that station, relieving Captain Peter R. Egan, Assistant Surgeon. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

EGAN, PETER R., Captain and Assistant Surgeon. By direction of the Secretary of War, on being relieved by Captain Borden, will report in person to the commanding officer at Fort Warren, Mass., for duty at that station, relieving Captain George McCreery, Assistant Surgeon. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

MCCREERY, GEORGE, Captain and Assistant Surgeon. By direction of the Secretary of War, on being relieved by Captain Egan, will report in person to the commanding officer at Fort Clark, Tex., for duty at that station, relieving Captain Charles M. Gandy, Assistant Surgeon. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

GANDY, CHARLES M., Captain and Assistant Surgeon. By direction of the Secretary of War, on being relieved by Captain McCreery, will report in person to the commanding officer at Fort Shaw, Mont., for duty at that station. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

GARDNER, WILLIAM H., Major and Surgeon. By direction of the Secretary of War, is relieved from duty at Washington Barracks, D. C., to take effect on the arrival of Major Joseph K. Corson, Surgeon, and will report in person to the commanding officer at Angel Island, Cal., for duty at that station. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

CRONKHITE, HENRY M., Major and Surgeon. By direction of the Secretary of War, relieved from duty at Fort Lewis, Col., and will report in person to the commanding officer at Fort Trumbull, Conn., for duty at that station, relieving Captain Robert J. Gibson, Assistant Surgeon. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

GIBSON, ROBERT J., Captain and Assistant Surgeon. By direction of the Secretary of War, on being relieved from duty by Major Cronkhite, will report in person to the commanding officer at Fort Sam Houston, Tex., for duty at that station. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

WOOD, LEONARD, First Lieutenanant and Assistant Surgeon. By direction of the Secretary of War, the leave of absence granted in S. O. 74, August 30, 1890, Department of California, is extended one month. S. O. 232, par. 7, A. G. O., Washington, D. C., October 3, 1890.

BAILY, JOSEPH C., Lieutenant-Colonel and Assistant Medical Purveyor, Medical Director of the Department. Granted leave of absence for one month. S. O. 86, par. 3, Department of Texas, October 3, 1890.

BYRNE, CHARLES C., Lieutenant-Colonel and Surgeon. Relieved from duty as attending surgeon at the Soldiers' Home, near this city, and will report in person to the commanding officer at Fort Sam Houston, Tex., for duty at that station. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

FINLEY, JAMES A., Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from duty at Fort Totten, N. D., and will report in person to the commanding officer at Jefferson Barracks, Mo., for duty at that station, relieving Captain William D. Crosby, Assistant Surgeon. S. O. 232, par. 8, A. G. O., Washington, D. C., October 3, 1890.

CROSBY, WILLIAM D., Captain and Assistant Surgeon. By direction of the Secretary of War, on being relieved by Captain Finley, will report in person to the commanding officer at Fort Pembina, N. D., for duty at that station. S. O. 232, par. 8, A. G. O. Washington, D. C., October 3, 1890.

MACAULEY, C. N. BERKELEY, Captain and Assistant Surgeon. By direction of the Secretary of War, relieved from duty at Fort Supply, I. T., and will report in person to the commanding officer at Fort Lewis, Col., for duty at that station. S. O. 233, par. 2, A. G. O., Washington, D. C., October 4, 1890.

CHERBONNIER, ANDREW V., Captain and Medical Storekeeper. By direction of the Acting Secretary of War, his retirement from active service on October 12, 1890, by operation of law, under the provisions of the Act of Congress, approved June 30, 1882, is announced. S. O. 240, par. 11, A. G. O., Washington, D. C., October 13, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending October 18, 1890.

BRAISTED, WILLIAM C., Detroit, Mich. Appointed an Assistant Surgeon.

WALES, P. S., Medical Director. Detached from temporary duty as member of Medical Examining Board.

AMES, H. E., Passed Assistant Surgeon. Detached from temporary duty as member of Medical Examining Board.

HERNDON, C. G., Surgeon. Ordered to Naval Hospital, New York.

PERSONS, R. C., Surgeon. Detached from Naval Hospital, New York, and to wait orders.

SCOTT, H. B., Passed Assistant Surgeon. Ordered before the Retiring Board.

PRICE, A. F., Surgeon. Detached from Naval Dispensary, Washington, D. C.

ANDERSON, FRANK, Passed Assistant Surgeon. Ordered to Naval Dispensary, Washington, D. C.

WHITE, C. H., Medical Inspector. Ordered to hold himself in readiness for duty on the San Francisco.

BRAISTED, W. C., Assistant Surgeon. Ordered to Army and Naval Hospital, Hot Springs.

SPRATLING, L. W., Assistant Surgeon. Ordered to hold himself in readiness for orders to the San Francisco.

SIGFRIED, C. A., Surgeon. Ordered to the Trainingship New Hampshire.

BLACKWOOD, N. P., Assistant Surgeon. Detached from duty in the Bureau of Medicine and Surgery, and granted leave of absence.

STONE, L. H., Assistant Surgeon. Detached from the New Hampshire and to wait orders.

EDGAR, JOHN M., Passed Assistant Surgeon. Ordered to hold himself in readiness for duty on the San Francisco.

GARDNER, J. E., Passed Assistant Surgeon. Detached from the Albatross and to wait orders.

BRIGHT, GEORGE A., Surgeon. Detached from temporary duty at the Naval Academy, and placed on waiting orders.

AYRES, J. G., Surgeon. Detached from temporary duty at the Naval Academy, and placed on waiting orders.

LUMSDEN, GEORGE P., Passed Assistant Surgeon. Detached from the Boston, and granted three months' leave.

AUZAL, E. W., Passed Assistant Surgeon. Detached from the Naval Academy, and ordered to the Boston.

SMITH, HOWARD, Surgeon. Ordered to appear before the Retiring Board at Mare Island, Cal.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 18, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	45	14
Scarlet fever	34	4
Cerebro-spinal meningitis	0	0
Measles	54	7
Diphtheria	53	15
Small-pox	1	0
Varicella	2	0
Pertussis	2	0

Insurance and Murder in England.—Children are now insured before they are born, and at the payment of one penny a week. This insures a sum which far more than covers the funeral expenses, and the same child is often insured in more than one office. Under such a system the father or mother may make a profit of three or four pounds on the death of a baby, to say nothing of what would be spent on food and clothes. The Bishop of Peterborough repeated a shocking phrase, which explains itself, and which would be only weakened by comment. They talk in a town which he did not and we will not mention, of "having a little funeral and a big drink." Now, of course, it does not follow that, because these things may be done, they are done, and some optimists argue that they cannot be done. There is, they say, the fear of the gallows—"S'il n'y a pas un Dieu, il y a toujours le gendarme"—and there is the doctor's certificate. To cut an infant's throat or give it prussic acid would not only be desperately wicked, but incredibly foolish. Insufficent food, and judiciously improper treatment in one or two small particulars, and the flickering light is effectually quenched. "Would any of your lordships," asked the bishop, "be willing to intrust a child of yours to a sick-nurse who had a pecuniary interest in its death?" A medical man wrote to the Bishop of Peterborough to say that he had for some time insisted on an inquest whenever an insured child died. What happened? He appeared as a witness, and was asked if he could swear that the child would have lived if it had been properly fed. He could not, and the verdict was "Death from natural causes," avoiding at least the awful blasphemy of "Died by the visitation of God."—*The Saturday Review.*

Attributed to the Wrong Cause.—The Chicago *Tribune* tells of a Missourian who died from having gorged himself with veal and hard cider. He was a member of several societies, all of which passed resolutions imputing his removal to Divine Providence.

SOME FURTHER REFLECTIONS ON PASTEUR'S ANTIRABIC INOCULATIONS.

BY JOSEPH DRZEWIECKI, M.D.,

LATE ORDINARY PHYSICIAN IN THE UNIVERSITY CLINIC OF THE HOLY GHOST HOSPITAL, WARSAW, RUSSIAN POLAND.

IN the last issue of the *Annual of the Universal Medical Sciences*[1] I find the following statement about hydrophobia:

"In speaking of an anti-Pasteur meeting in London, the *Medical Press* notes that, while all agree in their opposition, the objectors base their action upon distinct and antagonistic grounds. Thus far, the cause of the anti-rabists has been upon lines strikingly parallel to those of the anti-vaccinationists, and, while there are undoubtedly some intelligent persons who do not accept Pasteur's deduction, the probability is that the opposition will finally be confined to the smaller collection of unreasonable cranks."

The author of the above words should know that in science there ought to be no antagonism, but arguments. The history of medicine presents the best proof how many erroneous theories during a long time existed in our science, and we, who learn the past and know it well, should endeavor not to repeat the faults of our ancestors. Thus the theory of anticharbon inoculations, which not long ago created a great noise in the whole world, is now rejected, and, being injurious, is prohibited in Russia and Germany. Up to the present day the question of the antirabic inoculations counts many intelligent opponents, who continually raise their voices against this treatment, and therefore the question cannot be considered as settled.

From the above we must thoroughly examine Pasteur's theory and its arguments.

The *contagion* of hydrophobia, according to the present opinion, is claimed to be due to bacteria, which thus far has not been detected. As a solid body it does not diffuse through burnt clay, and on the other hand that it can be transferred by inoculation from one organism to the other is the best proof of its faculty of multiplication. However, it loses its power under action of heat, dryness, and in the presence of free oxygen. The chemical poisons have other properties: they diffuse through burnt clay, and are less affected by temperature, dryness, and oxygen, and cannot be transferred by inoculation from one organism to the other.

The contagion of hydrophobia, according to the opinion of Pasteur and his adherents, is principally localized in the brain and spinal cord, from which place it passes through the nerves; in much smaller quantity it exists in the salivary glands and in the saliva, but not in the tissues and in the blood, because the latter destroys it by oxidation.

Although the former experiments of Hartwig proved that the saliva is most and the nerve tissue least contagious, we must recollect that in ordinary conditions contagion enters the organism of animals and men by introducing saliva and not by preparations from the spinal cord; hence Pasteur in his experiments should pay attention to the former, and not to the latter.

[1] Vol. iii.

The foundation-stone of Pasteur's theory is a gradual accommodation of the organism to the gradually increasing virus, which is localized in the brain and spinal cord. According to Pasteur, the bacteria of hydrophobia, on being introduced into the organism, commence directly, but slowly, to travel through the nerves into the brain, and on their arrival there the disease breaks out. In ordinary conditions one, two, or more days elapse before the patient enters Pasteur's or his followers' institute. Immediately the inoculations of the dry cord of rabbits with graduated virulent properties are made, so that when real bacteria come into the brain it is insusceptible to their action. In this manner, according to Pasteur, there exists a bacterium race, in which the weaker the bacteria the sooner they enter the brain. A special kindness of the bacteria to Mr. Pasteur's theory! Yet some of Pasteur's adherents find the reason of the weakened bacteria coming sooner into the brain in their getting there by the circulation, but if we consider the oxidating property of the blood, and on the other hand the obstacle in the shape of capillary vessels in the lungs, we must agree that this theory is nothing but an empty phrase. Still more unintelligible is for us the dosing of the contagion of hydrophobia, as Högyes[2] is doing it, and whose experiments, as the adherents of Pasteur's theory affirm, are the best proof in favor of it. Högyes, too, makes use of the spinal cord of an infected rabbit, but instead of drying it to a gradually increasing extent to obtain various degrees of activity, he merely rubs it up with water containing chloride of sodium so as to make solutions varying in strength from one-tenth to one-thousandth (by weight). The dog to be protected is injected successively with these, beginning with the weakest. Permit me to ask, can contagion with its easy faculty of multiplication be dosed, as is done, with soluble chemical poison? Who can warrant that one bacterium may not in a short time produce millions?

The action of antirabic inoculations is not clear to us, and can in no way be explained. It is neither accustoming the organism to poison, as it does with morphia, cocaine, etc., because the dose of poison can be fixed exactly, whereas the exact quantity of rabic virus, on account of the multiplication of bacteria is uncertain and impossible to determine. The poison getting into the blood by absorption, the rabic virus only enters the nervous centres by passing through the nerves. The poison always produces its own peculiar symptoms, and being taken in increasing doses is always injurious to the organism; the rabic virus does not produce any bad symptom, but only salutary effects!

It is neither possible to detect any analogy between vaccination and antirabic inoculations, as some writers do without criticism: (*a*) Only healthy persons are vaccinated, while the antirabic inoculations are made on infected persons; (*b*) by vaccination we produce an artificial mild form of disease, in order to lessen the violence of the small-pox, when it breaks out, while the antirabic inoculations do not produce any disease; (*c*) the adherents of Jenner's method prove by statistics that vaccination mitigates the violence of small-pox, while, in spite of Pasteur's inoculations, a mild form of hydrophobia is not yet known.[2] Thus we see that we would vainly endeavor

[1] The Lancet, 1887, vol. ii., page 1185.

[2] Although Welch of Baltimore (Centralblatt für Bacteriologie, 1887) supposes that small-pox may be weakened in its form by vaccination during the period of incubation, yet his observations are delusions

to explain Pasteur's method by any of the accepted theories in medicine. It is something quite new and incomprehensible. Therefore the question arises, why Pasteur's method has found such great approbation and success? Above all it was recommended by the name and merits of M. Pasteur, and afterward by his statistics and experiments on animals.

Before we come to Pasteur's statistics we must first stop to consider experiments with prophylactic inoculations on animals.

It is well known that men as well as animals possess their own insusceptibility to hydrophobia and rabies, but this the experimentalists have never taken into consideration. Conscientious researches of many writers proved that only thirty-seven per cent. of infected dogs become mad,[1] or that of one hundred dogs bitten by rabid animals only one-third died of rabies, and two-thirds remained healthy. I ask, How is it possible to determine in the experiments whether a dog is susceptible to the virus or not? As there is no criterion, we have no right to affirm that only prophylactic inoculations secure him from rabies, because the same result may be the consequence of his insusceptibility to the virus. In this manner it is clear why in Frisch's experiments some dogs become rabid, and some not; those who were insusceptible to the virus did not become rabid, and the others, who were susceptible to it, became mad. By the same reasoning may be explained, why fifty of Pasteur's, and twenty-four of Högyes' dogs were insusceptible even to the strongest virus. Besides the experiments on animals are made—as already mentioned—with the dry spinal cord, and not with saliva by which the disease is transferred.

We come to the statistics. Trousseau taught his pupils that hydrophobia is a disease which very rarely occurs in the human race, and that in France, 20 to 25 cases of death occur each year from hydrophobia. Recent researches show that the average number of deaths per year in France, is 25; in Bavaria, 18 to 20; in Austria, 58; in England, 43; and in London, alone, 8.5. If we compare these numbers with the whole population, are we to regard them as serious enough to establish special expensive institutes and specialists? For health and security of life would be too expensive to society if, in order to secure twenty-five persons from hydrophobia in France, 1,700,000 francs are spent, while far more persons die from phthisis, small-pox, diphtheria, etc., and nobody thinks of establishing special institutes for these diseases.

According to Tardieu, Boudin, Brouardel, Thamheyn,[2] of persons bitten by undoubted rabid dogs only eight per cent. die, or out of one hundred, 92 remain healthy without any treatment.[3] Considering, however, that to Pasteur's Institute all bitten persons apply, even such as are not bitten by mad dogs, and that at least one-half of them were treated at home directly after the bite by cauterization or washing the wounds, and were so secured from bad consequeeces, it cannot appear strange to us that the mortality of eight per cent. must be considerably reduced, and the statistics given by Pasteur and others must not astonish us.

As observation showed, out of biting dogs there are six times more not rabid or suspected dogs than undoubtedly rabid, and if we are to speak of the one and the other, we must own that not eight per cent. but only $\frac{8}{6}$ per cent., or 1.33 per cent., should get rabid. Dr. Stanislaus Rybicki, in his article on the same subject published in the Polish paper (*Medycyna*, No. 47, 1889) mentions a very interesting fact. He served as "officer of health" during twenty-three years in the district of Skierniewice, and during that time he had occasion to observe 232 persons bitten by rabid dogs, of which, with exception of two, all were treated by cauterization of the wounds. Of this number only two died, and namely those who had not been cauterized, which makes only 0.86 per cent. Statistics is a two-edged sword, and more than once has led to false results.

According to Lutaud,[1] Pasteur and Grancher juggle with ciphers, and show that the mortality of hydrophobia falls to 1.5 per cent. If we, however, consider the above remarks, we cannot apply any value to such statistics. Lutaud from the very beginning of the introduction of Pasteur's method carefully noticed all cases of death after treatment in the Institute, and although a great part might have escaped his attention, yet those collected in 1886, 1887, 1888, and 1889 prove that *the mortality from hydrophobia in France after the introduction of Pasteur's method . . . increased.* According to his statistics,[2] in France alone 154 Frenchmen died of hydrophobia, of these 90 were inoculated in the Institute, and 64 not, making a yearly average of 38 cases of death, whereas up to the time of introduction of antirabic inoculations only 25 to 30 died in France, the best proof that the mortality increased. Of the detailed tables given by Lutaud, in which, besides the name, place of lodging, and age of every person, is also stated the date of bite, and day on which the treatment was concluded, and day of death, etc., by which may be seen that of Frenchmen alone the deaths were in 1886, 19; in 1887, 27; in 1888, 23; in 1889, 21; total 90. Of this number—according to Lutaud—31 died with symptoms of paralytic rabies, which he regards as a proof of the development of disease, not as consequence of bites but of preventive inoculations.

In the same opinion shares Professor Peter, whom I mentioned in my article on the same subject of last year. As to my opinion, the antirabic inoculations help in so much as they deprive the patient of fear, and how important this is is shown by facts published in *The Lancet* (July 6, 1889) under the title: "The Effects of Fear on the Development of Hydrophobia." However, the inoculations must be made with great precaution and fear lest they terminate in such fatal results as happened with charbon-inoculations in Odessa, where in consequence of the preventive inoculations 5,000 sheep died, so that the Russian Government, after due inquiries, prohibited this preventive method forever. Formerly the same results were obtained from preventive inoculations of syphilis in Sweden.

Summing up all the above we come to the following conclusions: 1. The theory of antirabic inoculations is quite new and cannot be compared either to gradual accustoming the organism to poison, or to vaccination. 2. The antirabic inoculations do not weaken hydrophobia nor prevent it. 3. The problematical effect of them arose on one side from the experiments on animals, whose insusceptibility to the virus was not regarded, and on the other from statistics of inoculations made unscientifically and with bias. 4. From the time of the introduction of Pasteur's method the mortality of hydrophobia not only not lessened but increased in France. 5. If the antirabic inoculations ever have any influence, it is only a removal of fear from the patients, but as we have no surety of their being not injurious they should not be applied for this purpose.

Warsaw, 87 Krakowskie Przedmiescie.

A Fortune in Teeth.—It is said the American dentists use in the form of gold filling for the teeth 1,800 pounds of gold, representing $450,000.

with which we meet every year in medical science. His observations have not yet been proved by anybody, and daily facts oppose them: (*a*) vaccination has no effect in the time of incubation; (*b*) and if it accidentally has, it produces only papules and not pustules, and the former do not at all prevent the inoculated from severe small-pox; (*c*) but if it happens that in this case the course of the disease is mild, it can be ascribed to nothing else but accident, as it is well known that persons even not vaccinated may have only a mild form of small-pox.

THE ROTARY ELEMENT IN LATERAL CURVATURE OF THE SPINE.

By A. B. JUDSON, M.D.,
NEW YORK.

The method of accounting for the rotation attending lateral curvature of the spine, which I proposed about fifteen years ago,[1] occurred to me when preparing a lecture on lateral curvature for the Women's Medical College in New York City. It seemed to me then, and I have seen no reason to change my opinion, that rotation takes place because the anterior part of the column, the bodies, are free to move laterally in the cavity of the chest and abdomen, while the posterior part of the column, the processes, are prevented from the same degree of lateral displacement by being entangled in the posterior parietes, composed of ribs, muscles, and fasciæ. This anatomical disposition of the parts is recognized when a subject is eviscerated on the dissecting-table. The vertebral bodies are seen projecting strongly into the cavity of the trunk, while the vertebral processes are fused into the parietes, as need not be mentioned to anyone who has dissected in this region. This arrangement is also seen in Fig. 1, which is copied from a drawing made by Mr. Alexander Shaw, for Sir Charles Bell's "Practical Essays."

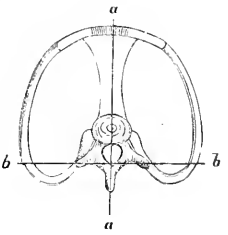

FIG. 1.

The rotation attending lateral curvature may be seen in the preparations found in every pathological museum. Curvature, with due rotation, may also be produced in a

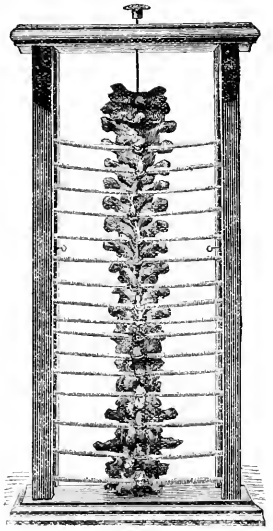

FIG. 2.

preparation like that shown in Figs. 2, 3, and 4, in which the vertebræ of a normal spine are assembled under mechanical conditions similar to those found in the body. They are strung on a rod which is flexible laterally, and the spinous processes are hindered from wide lateral excursion by elastic spiral wires. The column thus arranged, when subjected to downward pressure, exhibits rotary lateral curvature, and when the middle of the column is restrained we have a compensating curve with its appropriate rotation, exactly as we have them in the healthy or diseased spine.

When we consider a single vertebra in rotation it is seen that, as it moves away laterally from the median line, the body makes a wider excursion than the spinous process, the body moving three-fourths of an inch perhaps, while the process may move one-fourth of an inch; and this constitutes rotation. The vertebra does not have

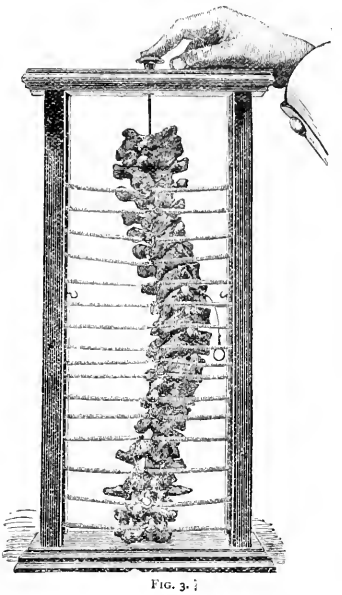

FIG. 3.

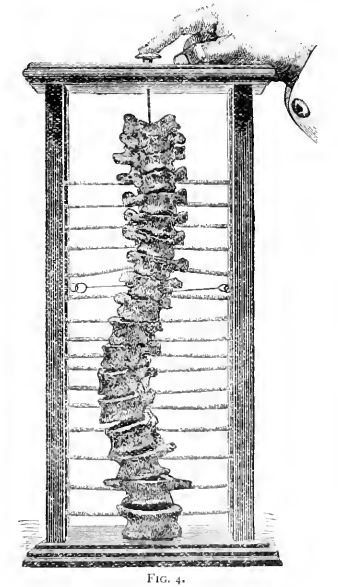

FIG. 4.

rotation on a central axis, as shown in Fig. 5, neither does it have rotation on a peripheral axis, as in Fig. 6; but it performs its rotation on an eccentric axis, one remote from the periphery, and still further removed from the centre, as is shown in Fig. 7.

[1] Transactions of the New York Academy of Medicine, 1876, pp. 315-330.

The lateral curvature is less in the processes than in the bodies, a very important point in an effort to appreciate the extent of the deformity, the gravity of the case. It follows logically, and is also true in practice, that an earlier diagnosis can be made by looking for rotation than for curvature.

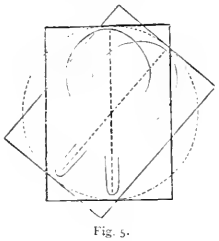

Fig. 5.

It will be found that this theory of the production of rotation agrees with all the phenomena which are observed in lateral curvature. For instance, the rotation is greater or less according as the curvature is greater or less; in the compensating curve the rotation as well as the curvature is reversed; and in the cervical region there is no rotation, because there is no cervical cavity corresponding to the thoracic and abdominal cavities.

It is an interesting fact that rotation is physiological as well as pathological, that is, it occurs in health as well as in disease. It is one of the functions of the normal spine. Lateral curving of the spine cannot occur without it. It adds a sinuous grace, which is difficult to describe, to attitude and action, as may be observed by close attention in the gymnasium. It may be easily demonstrated in a thin person by observing the prominence caused by the transverse processes on the side of the convexity of the curve, a prominence which has not infrequently, in patients affected by extreme lateral curvature, been mistaken for a morbid tumor.

It is probable that the apparent deflection of the track of the bullet in the case of President Garfield, was caused by the rotation of the spinal column accompanying strong lateral curvature. The track of the ball was found post mortem to traverse the vertebral body from right to left, and from behind forward, as shown by the direction of the arrow in Fig. 7. It will be remembered that the assailant was behind and to the right. I suppose the first shot was harmless, and caused the President to look over

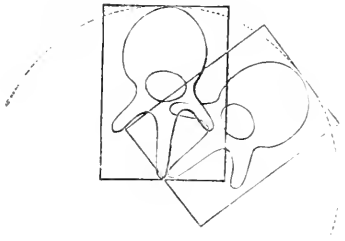

Fig. 6.

his right shoulder. Seeing the murderer preparing to fire again, he leaned strongly forward and toward the left, instinctively making the outline of his figure as small as possible, doubtless quickening his steps at the same time. This lateral curve of the spine threw the vertebral bodies far to the right, and they received the missile coming directly from behind. The concussion of the cord produced temporary paralysis, the victim fell, and the spinal column in straightening gave to the track of the ball the appearance of deflection.

The presence of rotation seriously complicates the question of treatment, because when lateral pressure is applied to the ribs for the purpose of straightening or supporting the column, a portion of the pressure, at least, reaches the column so far back, by reason of the articulation of the ribs with the transverse processes that it may even promote rotation, or at least prevent its reduction. If we could invade the cavity of the trunk and make direct lateral pressure on the bodies of the vertebræ, we might happily oppose at once the rotation and the lateral curvature.

An early diagnosis may generally be made by looking for rotation, which may be recognized by asymmetry of the scapulæ and by palpation of the chest between the two palms, which will reveal a difference in the diagonal diameters of the chest when curvature is slight or overlooked in the line of the spinous processes. If, for instance, there is rotation of the bodies to the right in the dorsal region, the diameter of the chest from the angles of the right ribs to the left mammary line will exceed the

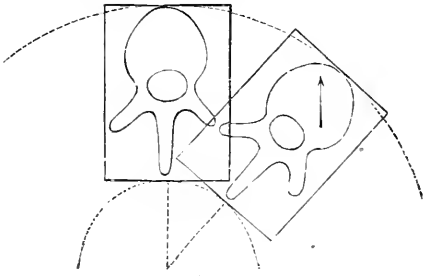

Fig. 7.

diameter taken from the angles of the left ribs to the right mammary line.

In the absence of accepted views of the etiology of lateral curvature, I assume that the deformity is an expression of inability on the part of the muscles (very likely of nervous origin) to hold the trunk erect. I am led, therefore, to advise the patient, in the first place, to give up tasks of all kinds, to practise reasonable methods of improving the health, to avoid treatment which involves muscular fatigue, and, instead of trying to hold the spine erect, to take and keep the recumbent position at will. In the next place, I advise the patient to adopt persistently, as many hours in the twenty-four as is possible, those attitudes in which the spinal column is as nearly symmetrical as may be, assuming that the increment then taking place will be on the right side of the dividing line between deformity and symmetry. The supine position, in which perfect repose is maintained with the nearest approach to symmetry, should be taken during the hours of sleep, and as much of the time during the day as is practicable. In the third place, I seek to produce lordosis of the dorsal and lumbar regions, on the theory that the patient is thus led to remove the imposed weight, or a part of it, from the bodies of the vertebræ which deviate widely from the median line to the articular processes, which, in virtue of rotation, remain comparatively near the median line. This may be done by suspension on the curved back-board, and also by using an air-pillow, about ten by eighteen inches (No. 2), placed under the back when the patient is supine, in such a manner that the shoulders may fall into the space between the air-pillow and the pillow for the head, and the pelvis may hang over the lower edge of the air-pillow. This position is to be assumed whenever the patient is recumbent, day or night.

In passing, I would say that suspension by the upper extremities, in any of the forms in which it is practised, is to be encouraged up to, but not beyond, the point at which it causes fatigue. In this way we can forcibly and directly separate the chest-walls for the purpose, first, of opposing the deformity, which lessens the capacity of the chest, and, second, of fortifying the health and strength, which depend largely on unimpeded respiration.

I am unable to express confidence in the use of braces applied for the forcible arrest or reduction of curvature. I can understand the application of force to straighten the knee, with pressure from before backward in the neighborhood of the joint, and counter-pressure from behind forward at points remote from the joint, on the bony levers which compose this joint; but am at a loss when I try to straighten by pressure a column composed of a score of short, jointed bones thrown into a double or triple

curvature, with the added complication of rotation in two or three directions.

Here, as on many other occasions in practice, one cannot help wishing that it were possible to do by the use of apparatus what we can do manually. Pressure made by a brace has the disadvantage that it is directed toward the centre of the body, with counter-pressure from the opposite side, also directed toward the centre. Force thus applied is useless as opposed to the rotation of the spinal column. But with the hands applied to the ribs the body may be rolled between the two palms and the pressure thus applied is not directed toward the centre and may possibly act against rotation. This can hardly be done by the use of a brace. Even if the apparatus is designed to make pressure not directed toward the centre, with a fixed point at the pelvis, with the purpose of untwisting the rotated column, it is to be feared that the force applied to reduce the rotation of one of the curves would do harm by promoting the rotation of the other curve, which is in the opposite direction, and an apparatus designed to act in both directions, with a common base at the pelvis, would probably prove to be too complicated to be useful in practice.

The only way in which I could hope to produce a favorable effect by direct force is to apply pressure by means of a steel brace from behind forward in such a way as to favor lordosis of the whole column. In this way it is quite conceivable that when the patient is erect both the primary and the compensating curves, and the rotation accompanying them, may be mitigated by a transference, as in the mechanical treatment of Pott's disease, of a part of the weight from the bodies, which deviate widely from the median line, to the processes which, by virtue of their anatomical connection, are held comparatively near the median line. Force thus applied would also affect the lateral processes on the convex side of the curve, which are rotated backward, before it reaches those on the concave side, which are rotated forward, and in this way it is conceivable that in a favorable case rotation may be forcibly and directly opposed in both the primary and secondary curves.

A general clinical view of the subject leads to the opinion that lateral curvature is not always a serious affection. It is certainly true that many persons lead happy and laborious lives with a marked deformity which is recognized by the dressmaker, and almost no one else. In view of this we can better reconcile ourselves to the admission that it is impossible to reduce a curvature which has passed the incipient stage. On the other hand, it is also true that in cases of exceptional severity, the kyphotic deformity is extreme, rivalling the worst results of spinal caries. Treatment should therefore be thorough and persistent in the case of a growing patient. We may thus reasonably expect to avert serious deformity, and approximate symmetry as closely as the nature of the case will admit.

A STUDY OF ONE HUNDRED CASES OF PNEUMONIA IN CHILDREN.[1]

By WILLIAM L. STOWELL, M.D.,

VISITING PHYSICIAN FOR DEMILT DISPENSARY, NEW YORK.

PNEUMONIA, inflammation of the lungs, or pneumonic fever, is a disease having a history running back as far as medical records extends. Its name has varied somewhat with the time, place, and special theories of observers. Its treatment has varied still more, yet the same disease may be recognized, the same things may be said of it as to prognosis and treatment as in times past.

In May, 1888, I began making a few notes and observations on pneumonia among patients in tenement houses in connection with my visiting for Demilt Dispensary. From that date until August 1, 1890, 146 cases of pneumonia came under my care. One hundred of these were children under ten years of age. These I have tabulated in various ways for my own study, and having no special theory to substantiate, I believe they are unbiassed records.

Hippocrates called the disease a peripneumonia and recognized that the pleura was always involved. In fact, he only applied pleurisy to an affection of the costal pleura. His writings are full of good observations on symptomatology for the present day, though his etiology is not up to 1890. For instance, one cause: "An inflammation of the lungs happens chiefly from drinking of wine, and great feeding upon codfish and eels; for these abound with a fat or oil very inimical to human nature." These excesses are no doubt predisposing causes. This learned author remarks that pneumonia and pleurisy do not occur under puberty, because there is less firmness of blood-vessels than in the adult. Probably he was not interested in practice of pediatrics.

Boerhaave[1] goes into lengthy discussion on the two varieties due to congestion, in the one case of pulmonary arteries, in the other to congestion in the bronchial arteries. A cause for this congestion he finds in "irritation of whatever exhales from plants and animals, whether living or dissolved by putrefaction after death . . . all fluctuates in the air."[2] Here he was not far from the theory of infection by germs.

A climate liable to sudden variations of temperature and moisture favors pneumonia. Huss[3] found in Stockholm that March, April, May, and June furnished forty-nine per cent. of cases; July, August, September, October, twenty-one per cent., and that November, December, January, and February gave thirty per cent.

Hippocrates found the robust usually attacked.

Grissolle found that half his rachitic patients had pneumonia. Scrofulous subjects are often attacked.[4]

The croupous variety is usually idiopathic, though of frequent occurrence in scarlatina, variola, rheumatism, and endocarditis.

The catarrhal is rarely, if ever idiopathic, and usually follows bronchitis and pulmonary collapse. It frequently occurs in measles, pertussis, phthisis or any diseases where a catarrhal condition exists in the lungs, or feeble respiration allows air-cells to be filled or collapsed. Typhoid or other fevers, keeping the patient long in bed, predispose to it; 65 cases in 167 of measles. Cited by Rillet and Barthez.

Of Gunsburg's 5,000 cases thirteen per cent. were under sixteen years of age.[5] Ziemssen speaks of 186 cases of primary croupous pneumonia in children, 117 of them under six years of age, 69 in next ten. He does not regard it as a rare affection. Reynolds says, "Pneumonia *is a very frequent* disease of early life."[6] The ages of my croupous cases were as follows: Under one year, 3; between one and two years, 9; between two and three years, 6; between three and four years. 3; under five years, 2; under six years, 4; none at seven years; at eight, nine, and ten years, each 1 case. Thus it will be seen the majority of cases occurred at two years, next at three years. After six years the croupous variety seemed to be uncommon. The youngest of these cases was three months old, and is the one mentioned later as having thrush.

Of 91 cases reported by Ziemssen, 41 were boys, 50 girls. These were all under four years. Of my 100, boys numbered 42, girls 58.

One attack does not afford immunity from another, though repeated attacks are not very common. Thirty-one of West's 78 cases had had a previous attack, while but 19 of Ziemssen's 201 cases were so blessed. One of my own cases, a girl, six years of age, had three attacks. I do not count it strange to be told a patient has been through two or three sieges, but rarely credit the statement unless I question very carefully about the attacks.

Intra-uterine pneumonia is likely to be syphilitic (Reynolds).

Sarjous [1] reports a woman very ill with pneumonia who gave birth to a child with the same. It died in five days, and was found to have, in addition, double suppurative pleurisy, pericarditis, and cerebro-spinal meningitis.

The actual cause has been given as "taking cold," exposure to strong wind irritating the lungs, irritation of many kinds, due to increase of fibrin in the blood, due to poison of unexcreted matters in blood, or associated with blood-poisoning from various germ diseases, lastly as due to a special germ.

The weight of evidence now is that inflammation of the lung is a specific infectious disease due to a micrococcus, *e.g.*, micrococcus Pasteuri, or the pneumococcus of Friedländer.[2]

Drs. Prudden and Northrup carefully studied 17 fatal cases of pneumonia following diphtheria, and concluded that the inflammation was due to breathing in quantities of the diphtheria streptococci.[3]

Exposure to cold when heated, residence in damp, badly-ventilated apartments, and general unsanitary conditions, favor it, for these are the conditions under which the infectious germs multiply and flourish.

Whether contagious as well as infectious is still doubtful.

The changes in the lung are usually divided into three stages, viz., engorgement, red hepatization, and gray hepatization; resolution or purulent infiltration might be added. These stages follow each other, or "may all coexist," [4] this being peculiar to infantile pneumonia.

In the catarrhal variety the stages are less well marked. Pulmonary collapse usually occurs, then hepatization, which as it softens may be termed gray hepatization.

Although it is said [5] that the lobular variety seldom occurs over two years of age, twenty-five per cent. of my cases were over two years and under ten.

Stokes speaks of a stage prior to engorgement, viz., arterial injection, which may give harsh breathing, high temperature, and subside rapidly. I believe I have seen several such. At all events, I have seen cases that answer the description and in which I made a diagnosis of beginning pneumonia. After a dose of antifebrin and a profuse sweating they recovered in a day or two. If there is such a thing as being "threatened with pneumonia," or "aborting" the disease, these cases must be examples. No such are included in my hundred cases.

The appearance of the lung is familiar to all. In the first stage it crepitates, is slightly heavier than normal, and the cut surface shows an undue amount of blood present.

In the second stage the lung is solid, mottled in color, does not crepitate, does not pit easily on pressure and being non-aërated it sinks immediately in water. Its cut surface is not smooth, but presents a granular appearance from the fibrinous masses that project from each air-cell. This fibrinous or croupous material was thought by Virchow to be derived from the blood-plasma, though now most observers agree with Cohnheim that the white blood-corpuscles play an important part and that there is also new-cell production.

The granular condition is less marked in children and the aged than in adults generally (Virchow).

Œdema surrounds the solid portions in lobular pneumonia and compensatory emphysema is found in the opposite lung in the croupous variety. The pneumonia of childhood differs from that of adults in that there are all grades and combinations of the two forms. Bronchitis, more or less extensive, usually prevails.

The brain is often congested and tubercles are occasionally found in tubercular subjects. The kidneys are congested and cloudy swelling may be found.

Rillet and Barthez speak of hemorrhage from stomach and bowels (Reynolds), though this cannot be common. The solidified lung may be distinguished from atelectasis by its paler color, absence of crepitation, and by absence of pleuritic involvement when near the surface.

The lobular form follows bronchitis usually and is symmetrically distributed. Several spots may be found in each lung. This is the form so common in children during dentition or complicating gastro-intestinal catarrh.

Fifty-six of my cases were of this variety. Those secondary to bronchitis I have not specially noted. Of those occurring as a complication, nine followed measles, eight followed pertussis and one followed diphtheria.

One of those following measles had pertussis at the same time. He had both lungs extensively involved and yet, in spite of lack of care and many adverse conditions, he finally recovered.

Of the croupous cases there were thirty. Of this number five were secondary to other diseases, as follows: To scarlatina two, to pertussis one, to thrush one, and to diarrhœa one. Of these cases all recovered. The total secondary cases were twenty-four, of whom ten died. The ten were all of the catarrhal variety.

It is generally believed that the croupous pneumonia chooses the right side oftenest. Meigs and Pepper say the lower lobe, but Vogel thinks this a mistake of normal for abnormal, as the right side respiratory sounds are always most distinct. Grissolle claims that the right upper lobe is affected two and one-half times to the left once. Of my own cases fourteen occurred on the left and thirteen on the right side. The left upper lobe two, and left lower six times. Right side, upper lobe five, middle lobe one, lower lobe three times. Entire left lung six, and entire right lung four times.

The right middle lobe is said by Walshe [1] to be inflamed in endocarditis or blood-poisoning. Neither complicated the case mentioned.

As we first come before the pneumonia patient we observe his rapid respiration. Not necessarily dyspnœa, for this is caused by non-aëration of the blood; a child may, by breathing fifty times a minute, keep his blood oxygenated, but if his heart fails dyspnœa results and the little patient becomes cyanotic, the lips blue, fingers and toes dark and cold.

The breathing is catching in character in the croupous form, owing to the pain caused in the inflamed pleura.

Grisolle thinks the cyanosis of the face may be due to the pressure by hepatized lung. The ratio of inspiration and expiration are reversed, and are nearly equal in time. The ratio between pulse and breathing is also altered. In place of 4 to 1 we have 2 to 1—*e.g.*, in a case aged two and one-half years, with measles, who on the fifth day had a respiration of 102 to minute and a pulse of 181. This was a fatal case of double lobular variety.

The *character* of the pulse is more important than its frequency, and relatively it is more rapid in children than adults. It is sometimes irregular in force, without being an alarming symptom. Should it be intermittent, however, the outlook is grave.

We now listen to the chest, and that without the child making objection. He is too busy with breathing to be annoyed by the examination; his whole attention is on the one object, and in marked cases the alæ nasi dilate, and he "expands his nostrils like a horse upon the course" (Hippocrates). Perhaps he will wince a bit if the examiner's head is pressed too heavily against the chest and increases the pain.

Pain is complained of by older children, sometimes being located about the chest, if the upper part of the lungs be affected, but probably felt in the stomach if the lower lobes are inflamed. Still "it is a disease which has more danger than pain" (Celsus). Broncho-pneumonia is accompanied by labored breathing, but rarely pain.

[1] Quoted by Reynolds, p. 196.

The skin is usually hot, though a little moist, especially about the head. Profuse or early sweating are forecasts of evil, for they indicate prostration. Profuse sweating ending in quiet sleep at the crisis means recovery

The face is flushed, Gubler says most so on side of inflammation, but Rillet and Barthez, with most others, say the flush is most bright on the opposite side. Herpes appears about the mouth and nose, and is regarded by the laity as a good sign, as "the fever is said to be breaking out." It is uncommon in children. I find it specially noted in but one case, nine years old, but feel sure I have seen it oftener. This boy also had rusty sputum.

The urine is diminished in amount, and contains an increase of urea with diminution of chlorides. Hippocrates considered it a fatal sign if the urine became pale in color before the fourth day—*i.e.*, before the crisis was passed.[1] Parks thinks the great increase in urea may be the cause of the diarrhœa so often seen.

A mild diarrhœa may be beneficial, as it is a natural method of getting the expectoration out of the body, it being well known that infants and young children will not spit out what comes from the lungs. Infants often vomit it, and it may then appear reddish or prune juice in character.

A profuse diarrhœa, or persistent, early in the disease I regard as a bad prognostic. The appetite is impaired, and many cases begin with vomiting. One half do so according to Rillet and Barthez. Not so common with my cases. The tongue is coated, often thickly, but we do not now trace any direct relation between the character of the tongue and parts of lungs affected, as did some older writers.[2]

Headache, restlessness, and even delirium are common early in the disease, but cause no alarm. Late delirium is grave. Convulsions are not uncommon as an initial symptom in the croupous form, occasionally also in course of any other disease to announce the catarrhal form. These nervous symptoms are due to cerebral congestion and seem to bear a relation to amount of lung involved.

The cerebral symptoms appear to be most common when the apices are affected and may in fact overshadow the symptoms referable to the lungs. This has given occasion to some writers to speak of a class of "cerebral pneumonia" cases (Rillet and Barthez). Latent pneumonia is merely overlooked pneumonia, lost sight of because cerebral or digestive symptoms predominate.

Temperature, as a rule, is much higher in croupous than catarrhal and usually ends in the former by crisis. I find among my cases one of broncho-pneumonia, aged thirteen months, with temperature 104.5° F. on second day. Another four and one-half years old, temperature 104.4° F. on second day. This case was a month in convalescence. A case of the lobar form, aged fifteen months, with temperature 105° F. on second day. As against these, a case (not of the 100), aged thirteen, with temperature of 102.3° F. on second day. These examples go to show that the temperature varies markedly in individual cases. The crisis usually occurs on about the seventh day in croupous, there is no crisis in catarrhal pneumonia. My cases nearly all terminate by lysis—croupous as well as catarrhal.

In the beginning pneumonia may be mistaken for one of the fevers or indigestion. If the pain is marked, pleurisy may be mistaken for it. It is often next to impossible to distinguish, as we know there is bound to be at least a little roughening of the pleura over the solidified lung. Grisolle is authority for the statement that fifteen per cent. of cases do have effusion into the pleura.

The crepitant râle may readily be mistaken for pleuritic friction, and I believe there are few cases where the two diseases are very distinct from each other.

Cough is dry and irritating in early stages, but later becomes moist and soft. This may aid in diagnosis from pleurisy, as the cough would cease entirely during the stage of effusion in the latter. Doubtless rusty sputa occurs in children nearly as often as in adults, but we rarely see it, for reason given above. The young child swallows what comes up in the throat. "Rusty" or "prune-juice" expectoration was noted in three of my cases, aged three and one-half, nine, and two years respectively. The nine-year-old also had herpes and began with a chill. In all respects behaved like typical pneumonia of adults.

"All diseases must terminate in one of three ways, viz., in health, death, or another disease" (Boerhaave). Most croupous cases terminate by the first, *i.e.*, health. Many catarrhal cases died, the percentage varying with diseases which they complicated. Those who die succumb to heart failure, to general exhaustion, or diarrhœa, some may perish of convulsions or delirium and a few to failure of kidney function. Some die in coma. Croupous may terminate in abscess or gangrene. I recall two cases of abscess in lung, but not any such in this one hundred. Both made perfect recoveries. Dilated bronchi which simulate cavities are often seen, especially in cases which had pertussis. Scrofulous and rachitic patients make slow recoveries and many such become tuberculous.

"Double pneumonia is more liable to terminate in sudden death than in suppuration and resolution."[1] Very fat children have been thought bad subjects. I regard the prognosis grave in these children having valvular disease of the heart, as they often have a hypostatic form of pneumonia. Very weak infants, in whom the pneumonia begins by simple collapse without bronchitis, rarely do well.

Treatment has been heroic, palliative, and expectant. Blood-letting was formerly practised, even in cases of children where the pneumonia occurred with measles or scarlatina. Then came tartar emetic treatment, sometimes alone, again in conjunction with venesection. Under this regime Dietl's mortality was twenty-two per cent., while Wunderlich with bleeding obtained a mortality of 6.38 per cent. Such a difference in results makes us question the cases somewhat.

Among drugs, mercury, potash, turpentine, digitalis, chloroform, aconiti, veratria, and the alkalies each have champions. Cold, in form of bath, sponging, pack, and compress, or ice-bag, each have much in their favor.

Although Dietl had a mortality of twenty per cent. with bleeding, Huss gives only 11.54 per cent. for same treatment. Dietl with expectant treatment gives 7.4 per cent. of deaths. Huss, with no bleeding treatment, gives 10.21 per cent. of deaths. The latter's statistics are from hospital records of sixteen years. Laennec had a mortality of but three per cent. by tartar emetic. Now the two methods most popular are expectant and antipyretic. Under the routine treatment Ziemssen's mortality was 25.2 per cent., by antipyretic methods he reduced it to 16.5 per cent. By my table the mortality was but sixteen per cent. for all kinds of cases, complicated and idiopathic and without selection. Yet it is three times greater than Laennec had.

Antipyretic treatment lessens fever largely by depressing the heart, and therefore Ziemssen says that it is a *sine qua non* of this treatment that the patient should have wine suitable to age, etc. Why give a depressant and stimulant at the same time? Valleix reported[2] 127 deaths in lobular pneumonia of 128 newly born children in Parisian Foundling Asylum, while Rillet and Barthez had a hospital mortality of one in seven. West gave, in 1843, 13.6 per cent. as usual mortality. Meigs and Pepper, 1879, for preceding ten years found it to be 5.44 per cent. under fifteen years of age. Wide difference again in figures.

The child with pneumonia dies from want of oxygen and from excess of CO_2. Can we increase one and diminish the other without expense of force to the sufferer?

[1] Quoted by Boerhaave, vol. viii., § 830.
[2] Hippocrates.

[1] Boerhaave, vol. viii., § 835.
[2] Vogel: Diseases of Children, p. 295.

Acting upon the belief that the disease cannot be aborted, any more than typhoid fever can, I have tried by common sense treatment to make the little patients comfortable and to aid a speedy and favorable termination of the disease.

In cases of marked headache and delirium at the onset one or two doses of antifibrin have proved beneficial. If the temperature has not been more than 103° F., and no symptom has been unduly prominent, I administer small doses of aconite or alkalies. In the croupous form pain is usually present and may be relieved by hot poultices on the back. If the attendants are careless poultices should not be ordered. When the inflammation is most marked anteriorly a cold compress is more easily applied and though unpleasant for a moment is very agreeable afterward. It is not so heavy as flax-seed nor so uncleanly. The labor of lifting a heavy poultice sixty times a minute is not a health-producing exercise. As a rule poultices are not helpful for a very long time in lobular pneumonia. Better rub the chest well with a slightly stimulating embrocation and put on sheet wool and an oiled-silk jacket. Flannel should be worn throughout.

At the time of crisis digitalis and an abundance of concentrated food should be given. In adults alcohol is usually given, as "it is not only a whip to the heart, but oats besides, because it supplies the organ with oxygen, without which muscular work is impossible."[1] In children the state of nutrition and of glandular activity is different and I believe they will take and assimilate meat extracts better without than with alcohol. We know that digestion is very imperfect in the presence of alcohol, so that the patient must live on that mainly if he takes much of it. Digitalis or muriate of ammonia will physiologically whip up the flagging heart, and digestion of peptonized milk or meat extracts go on at the same time.

The diarrhœa may be checked by a Dover's powder better than by alkalies. The cough may be lessened by those drugs that are volatile and pass readily out through the lung, and also by vascular depressants which tend to keep mucous membranes moist. When pneumonia is resolving cough should be favored, not checked. For this purpose administer ammonia or give an occasional emetic.

Of the 100 cases, 84 recovered. Of the 17 fatal cases 3 were of idiopathic lobar form, ages one and a half years, two years, and six years. In the two last mentioned, the pneumonia was double. The boy, aged six, died on the twentieth day of his illness, of diarrhœa.

Three of those who died of catarrhal pneumonia were idiopathic cases; their ages, ten months, fourteen months, and four months. The latter a hand-fed baby. Five died of lobular pneumonia following rubeola; ages four, five, two and a half, two and a half years, and one nine months. One, two and a half years of age, died in convulsions.

Five died of lobular pneumonia secondary to pertussis. Their ages were twenty months, twenty-two months, two years, two years, and ten months. It will be observed that the coexistence of these two diseases is very fatal to children of two years of age or younger; nevertheless, one aged two years and one aged seven months did recover.

One case of pneumonia and pertussis was saved by a dose of morphine at night, securing it a little rest. She had taken bromide of potash all the time for the pertussis. Improvement began from the first dose of morphia.

My conclusions are: The results of treatment are not so unpromising in crowded unsanitary quarters as would be expected. Common-sense or palliative treatment is best. Alcohol is not needed in pneumonia of children. Antipyretics weaken a child more in proportion than an adult. Moderate bathing or sponging of surface makes the patient comfortable, and in so far aids recovery. Many mild cases become severe and fatal in spite of treatment, and no cases are so bad that the physician should not do his utmost to save. Many severe cases get well with little care and less medicine.

I come at last to Ziemssen's conclusion, "that nature cures, and the only duty of the physician is to maintain life until this cure is effected."

136 East Eighteenth Street.

SOME OBJECTIONS TO COCAINE IN GENITO-URINARY SURGERY.[1]

By JOSEPH B. BISSELL, M.D.,

Attending Surgeon Bellevue Hospital, Outdoor Department.

Cocaine is of almost universal application in such operations as circumcisions, internal urethrotomies, meatotomies, etc., and is usually attended with complete success as an anæsthetic. There are, however, some disadvantages following the use of the drug, and I wish to briefly relate a few of them.

Since cocaine has been in use it is not uncommon to find, after an internal urethrotomy, one or two pieces of mucous membrane clinging to the urethrotome. They are usually found in the angle between the dilating-bars and the short cross-bars.

In these operations the Otis urethrotome, an instrument which is very nearly perfect, is always used, and used with the utmost care. After the cutting, the bars are only closed sufficiently to admit of its withdrawal. In about one-quarter of all the cases there was found caught in the instrument one or more pieces of membrane. In some cases the portion torn out was of considerable size. In a recent operation it was over half an inch long and nearly a quarter of an inch at its widest point.

Where ether is used in the internal operation with perineal section this accident is not noticed. In order to be still more certain that the cocaine caused the trouble, I made applications of cocaine to normal urethræ, and into urethræ with large calibre strictures, as if about to perform internal urethrotomy, waited the usual time for it to absorb, and then, through the endoscope, observed the condition of the urethral wall. There was a little more difficulty than was natural in entering the proper-sized tube. The mucous membrane was blue and congested, and pointed into the opening of the tube. In the pathological urethræ these appearances were most marked.

This narrowing of the canal and fulness of the mucous membrane would account for the frequency with which the latter is caught and torn away by the smallest closing of the bars of the instrument. Future stricture or permanent contraction of the penis will be a very natural result of this laceration. Hemorrhage after the operation is another disadvantage of cocaine. Bleeding during the first night is more likely to occur after cocaine anæsthesia than after ether or chloroform, as can be observed in cases of external section. This hemorrhage is not of much importance in hospitals or where a competent nurse is in charge; but when the care of the patient is left, as it often has to be, to a lay friend, it may be a very serious matter.

In circumcision cocaine rarely gives trouble during the operation. If the solution is injected too close to the line of the cut, the swelling it causes may obscure the edges and leave a ragged and irregular line of union

The extravasation of blood, which is almost unavoidable where the cocaine is injected into the subcutaneous tissue, is objectionable. In some cases superficial sloughing of localized points may result from this extravasation and make the healing slow and troublesome.

A very serious objection to cocaine in circumcisions is in children or in very nervous patients. The sight of the instruments, the dressings, the pain of the hypodermic punctures, and feeling and hearing the cutting and sewing up of the wound will cause severe shock in a delicate and

[1] Read before the Charity Hospital Alumni Association, October 14, 1890.

sensitive child, and may frighten him into hysterics or even convulsions.

Chloroform is so easily given, and so harmless in children under ten years, that it or ether ought to be used in preference. Idiosyncrasy may account for certain cases in which the drug, however skilfully applied, does not completely anæsthetize.

Other cases occur in which the tissues, owing to pathological changes, do not absorb the solution rapidly enough, or sufficiently, in the quantity it is safe to use, to cause complete freedom from pain.

Cocaine poisoning is always possible, even with moderate quantities of the drug.

Some people are much more liable to cocaine intoxication than others. One of my patients, whom I circumcised for an old inflammatory induration of the foreskin, developed serious constitutional symptoms; but after waiting over half an hour I operated without any local anæsthesia whatever. The patient was a man, twenty-eight years of age, and of good habits. I injected forty minims of a six-per-cent. solution. During the operation, which lasted about three-quarters of an hour, he complained of dizziness, inability to see, and nausea. His pulse was 100 to 120, full and bounding. After the operation he went soundly to sleep, and, though easily awakened, he was unable to walk for several hours. He recovered completely in about six hours after the operation.

ELECTROLYTIC AND OTHER NEW USES OF STORAGE ELECTRICITY.

By ROBERT L. WATSON, M.D.,

NEW YORK.

As far as I am aware, storage electricity has not been used for medical purposes, except for cauterization, running motors, reducing tonsils, etc. But in my experiments with this form of electricity, for the past few months, I have found it may be used for many other purposes to which dynamic electricity has been applied. I have used the ordinary batteries charged by Ford & Co., but if one is on the line of the Edison underground system he may charge his own. The capacity of my batteries is 100 ampère hours, each with a potential of about two and one-quarter volts, which is the voltage of all storage cells, of whatever size. For convenience I placed them in an ordinary music cabinet. To complete the outfit, I removed the induction coil from my faradic battery and glued it to the cabinet, using it as with the ordinary battery. This gave me a complete electro-medical outfit for all purposes, at a comparatively small outlay. Besides employing my battery as a cautery, a use long since familiar to the profession, I have been able to employ it with uniform success:

1. As a galvanic current. In order to make this use of it, however, one must have at least three cells or six volts, and the sponges must be moistened with water. Three cells are necessary if the current is to be felt; but in order to produce positive results, it is not always necessary to use so many cells, and I personally have no doubt that a one-cell 10 ampère hour battery would give good results, although this current cannot be felt. I have observed in my experiments that when I puncture the skin of the leg with one needle and that of the arm with another, on suddenly closing the circuit a severe shock is felt, even when only one small storage cell is used; but when the punctures are simply into, but not through, the cuticle, no sensation is appreciated. Erb says in his work that single-cell galvanic batteries do good in paresis, but require time.

2. As a faradic current. In this case the poles of the storage cells must be connected with the induction coil, which, of course, changes the constant current to the faradic. If the armature of the induction coil does not vibrate, there is too much current, and a rheostat will have to be introduced. This will remedy the difficulty and allow the storage cell to be used with any coil, of whatever resistance or size. But the most satisfactory use is:

3. In electrolysis applicable in the removal of nævi, fibrous growths, and other excrescences. My method is to puncture just beneath the skin, at the base of the growth, with two common needles as electrodes, one on either side. The current is then allowed to pass about five minutes, or until the growth undergoes such change as will indicate to the experienced operator that the current has produced its proper effect.

In seven or eight days with the smaller growths, and proportionately longer time for the larger ones, the excrescence drops off, leaving an open sore which rapidly heals. If the first application should not be successful, a second one may be made a few days after. In the second application it is advisable to let the current run at right angles to the first one. It is curious, but nevertheless a fact, that when a milliampère meter was introduced in the circuit with the nævus, no current was indicated whatever, no matter how close the needles came together (if they absolutely touch the points will become hot and cauterize). The meter indicated nothing, yet there must have been a current, for the nævus disappeared. No doubt a capillary electrometer would indicate a current.

In operating with this storage, or low-tension, current, one must be sure to have his wires large enough to carry the full current, otherwise no appreciable results will be obtained. A good way of ascertaining whether the wires are of proper size is to put the cautery in the circuit first, and if it works the electrodes are undoubtedly all right

The use of this form of electricity causes no pain and leaves no appreciable cicatrix, but does have an electrolytic or catalytic effect. Amory, in his work, speaks of the successful use of the galvanic current in reducing moles. But he obtained his results only by the use of many cells, while one cell of a storage battery of the same size as one of his will do the same work. But it has a larger ampèrage, and this proves to my mind that what is required in electrolysis is quantity of electricity, not voltage or tension.

Erb speaks of the electrolytic use of the galvanic, faradic, and magneto-electric induction. But I know of no literature on such use of the storage current. He further says the galvanic current affects muscles, nerves, and deep organs because it is deeper, and therefore more penetrating, while the faradic (the storage) is more superficial in its action. Amory also says that the weaker currents should be used in connection with the strong in cancer, because the weaker penetrates tissue which the stronger does not.

Since the storage battery gives a weak current, it should be useful in galvanization, according to both Erb and Amory. Moreover, my observations seem to bear out the opinion of Gröh, given in Amory's work, that a battery arranged for heating would be the best for electrolysis.

Finally, from experiments I am now conducting, I have no doubt but that storage electricity will find its fifth use in antisepsis.

We see, then, that storage electricity can be used not alone for purposes of cauterization, but for galvanic, faradic, electrolytic, and probably for antiseptic purposes. And what is required in electrolysis is not voltage, but quantity of electricity and time.

Case I.—J. D. M——, twenty-nine years of age. Mole on forehead since birth. Passed 100 ampères five minutes, with needles, just beneath skin; it became inflamed and changed shape. Did not disappear. A week later operated again, with same current applied twice at right angles to each other. In three days mole fell out like a kernel of corn from a cob. In about two weeks wound was healed up and left no cicatrix.

Case II.—Captain B——, sixty-nine years of age. September 9th, has had a small fibrous tumor on inside of left cheek, near Steno's duct, due to sharp edge of tooth. Is afraid of cancer. Passed a current of 100 ampères three minutes; it swelled up, became white, and, finally red. Then passed 4 volts and 200 ampères for three minutes at right angles to the other current, when a waxy-looking material poured out from one pole, and blood from the other. No pain.

September 22d.—Gone down to about one-half size. Somewhat sore. Passed current again.

October 1st.—Gone down about one half more. Says it is too slow, therefore took rest off with electric cautery.

Have had several other similar cases, but these will suffice for an illustration.

Case III.—G. A. W——. Ten years ago had a pimple removed from his face which was called a cancer. For the past year he has had an indurated sore with a discharge of pus. Diagnosticated by a New York specialist as rodent ulcer. Rather painful, and very annoying.

July 25th.—Electrolyzed with two steel needles for ten minutes; current, 2 volts, 10 ampère hours.

August 26th.—Seems about same. Passed current again. Pain ceased when I got through.

September 8th.—Seems to be larger; troublesome as before. Passed current of 10 ampères twice for ten minutes each.

October 1st.—I hear from the family physician that it is better, and seems to be taking on a healthy action. This patient had nervous prostration very severely, from which he has not yet recovered.

PHLEBOTOMY AS ONE OF THE MEANS IN THE TREATMENT OF INSOLATION, WITH A REPORT OF FIVE CASES.

By H. A. HAUBOLD, M.D.,

HOUSE-SURGEON, ST. VINCENT HOSPITAL, NEW YORK.

Most text-books divide all cases of insolation into two kinds, namely the sthenic form and the asthenic form. All the cases herein described were of the sthenic variety, and although the symptomatology has been most accurately described, a recital of the phenomena observed in these cases is pardonable, because of its important bearing on the rationale of the means employed. The usual history is that the patient was exposed to great heat (not necessarily solar heat), experienced a feeling of giddiness, and soon became unconscious. The face is dusky or flushed, eyes either strongly rotated upward, or in a condition of violent nystagmus. Conjunctivæ congested. Respiration is slow and stertorous. Muscular rigidity is well marked. This rigidity in some cases amounts to opisthotonos, in others the contractions are sufficiently intermittent to suggest an irritative cerebral lesion. Arterial pulsation rapid, full, and bounding, plainly visible in carotid and temporal arteries.

Cases of this kind present most striking conditions when seen early in the course of the attack, and are often mistaken for epileptic or apoplectic seizures. The temperature is a very important factor in this disease. It rises often to 108° to 109° F., and even 110° F. is not an uncommon event. A temperature of 110° F. is supposed to be positively fatal, or, to quote a well-known lecturer: "When a temperature rises to 108° or 109° F., entire recovery never takes place." When one realizes that an individual, in possession of physical vigor, may, suddenly and almost without the slightest premonition, be thus stricken, I think the importance of this subject is sufficiently emphasized.

Case I.—Admitted June 26, 1890. J. K——, blacksmith, forty-four years of age, was found unconscious on the corner of Varick and Downing Streets. He had been working at his forge all day, and fell in the street while on his way home. He had not been drinking on admission. Face flushed very deeply. Pupils contracted; skin dry and hot. Respiration slightly stertorous and increased in frequency. He could be aroused with difficulty. Temperature, 107° F. in rectum. Pulse, 145, full and bounding. Blood to the extent of twenty ounces was drawn from the left arm, a compress placed over the wound and the extremity bandaged from the fingers up. The patient was now placed in cold bath (60° F.) for fifteen minutes, at the expiration of which time he was placed between wet sheets for fifteen minutes longer. At the end of the thirty minutes thus employed his temperature had fallen to 101° F.; pulse, to 110. Ten grains of antifebrin in one ounce of whiskey was now administered, and this dose repeated in one hour. Two hours after admission his temperature was 98½° F. in rectum. Pulse, 88. Mind perfectly clear. There were no sequelæ apparent, and he was discharged cured in three days. I saw him one month after the date of his discharge, he was then engaged with his daily labor, as he has been since the day following his discharge.

Case II.—Admitted July 30, 1890. M. N——, aged thirty-seven, laborer. Patient found unconscious on Thirty-sixth Street, between Fifth and Sixth Avenues. No history could be obtained on admission. Patient comatose. Temperature, 108½° F. in rectum. Pulse, 140, full and bounding. Surface dusky, and breathing stertorous. Twenty ounces of blood drawn. Patient put in cold bath. After fifteen minutes in the bath he urinated and defecated involuntarily; his pulse, 120, but feeble and intermittent. Temperature, 103° F. Administered tinct. digitalis, ℥ xx., and brandy, one ounce, hypodermically. He was then placed in wet pack and left there for thirty minutes. Consciousness returned while in pack. At the end of one hour from time of admission his temperature had fallen to 101° F., and his mind was perfectly clear. His temperature varied between 101° and 100°, in the course of the next few days, during which time he took, morning and evening:

℞ Quin. sulph..... gr. x.;

and three times daily,

℞ Kali iodid ..... gr. xv.
Kali bromid..... gr. xx.

There were no untoward symptoms at the end of a week, and he was discharged August 9th, cured.

Case III.—M. M. H——, aged thirty years, admitted August 1, 1890; bricklayer. Was working on the new wing to St. Vincent's Hospital, exposed to the full glare of the sun. He had complained of slight vertigo and some indefinite disturbance of vision before the attack, and at 11:30 o'clock he suddenly fell down, unconscious. He was at once conveyed into the hospital. On admission, patient presented substantially the same symptoms as recorded above. The muscular rigidity amounted to opisthotonos. Temperature, 109½° F. Pulse, 150, full and hard. He was placed in the cold bath at once, and sixteen ounces of blood drawn from the arm. Temperature fell to 102° F. in thirty-five minutes. Then patient was put in wet pack for thirty minutes longer, and liq. morp. Mag. administered for his restlessness. The evening of the day of admission his temperature was 101° F. Pulse, 124. Ordered quin. sulph., gr. x., A.M. and P.M., and spirits frumenti, ℥ vi., in twenty-four hours. On day following his temperature was 100½° F.; pulse, 68. After this the temperature gradually fell and became normal. On evening of fifth day it rose to 100° F., but was normal, and remained so until his discharge, one week later. No sequelæ followed that were then apparent.

Case IV.—E. B——, aged fifty-four, coal heaver. Admitted August 1, 1890. While at work at foot of West Eleventh Street he suddenly fell in a fit and became unconscious. Was conveyed to hospital by ambulance. On admission, patient comatose. Had clonic spasm which simulated status epilepticus. In this case temper-

ature rose to 110½° F.; pulse, 150. Patient put in cold bath and eighteen ounces of blood drawn. His temperature fell about 1° F. every eight minutes while in the bath, and when it had fallen to 103° F. he was put in wet pack. He became conscious while in wet pack, but his pulse was feeble, beating 116 per minute. Brandy and digitalis given hypodermically. His temperature fell to 102° F. that evening. Ordered quin. sulph., gr. x., twice daily; spirits frumenti, ℥ viij. in twenty-four hours. Next morning his temperature was 103½° F., but fell to 100° in evening. Then it became normal (pulse, 80) and remained so until his discharge, ten days later. No sequelæ.

Case V.—J. O'B——, aged thirty-two, laborer. Admitted August 4, 1890. Patient brought to hospital in unconscious condition. No history. Muscular rigidity, coma, etc., well marked. Temperature, 109½° F.; pulse, 140. Patient put in cold bath and bled to amount of sixteen ounces. In twenty minutes temperature fell to 103° F., and after fifteen minutes in the wet pack it was 100½° F. Next morning temperature was normal; pulse, 78. He made an uninterrupted recovery and was discharged, cured, at the end of a week. No sequelæ.

Do not these cases illustrate the efficacy of bleeding? An important objection to an affirmative answer is, that the accessory means employed might have been sufficient to produce the beneficial effects. But inasmuch as they have failed to do so heretofore, no unusual claims can be made for them in this instance. Moreover, such immediate impression as bleeding produced in these cases cannot well be attributed to the bath alone. Again, the administration of antifebrin has not been followed by such immediate effects in previous similar cases treated in this institution.

The importance of immediate radical treatment is shown in a case that came under observation during the treatment of the cases recorded above. This patient was in collapse when first seen, and died so soon after admission that no therapeutic measures could be employed.

The ambulance surgeon is impressed with the necessity of bringing these cases to the hospital as rapidly as possible for treatment. The bath is situated in the hospital yard, the patient is stripped in the ambulance, and transferred directly to the bath and bled. This point is well illustrated in Case III. This patient was attacked while at work on the hospital building, and was seen within five minutes from the beginning of his attack. Even then he was profoundly comatose. Temperature, 109½° F.; pulse, 150. Thirty five minutes after bleeding his temperature was 102° F. I cannot think of any other antipyretic means that could have acted as promptly and as efficiently as the bleeding did in this case.

In Case I. the patient was not quite comatose. He was bled before any other means were employed, and he became conscious before his arm was finally bandaged.

Case IV. was the most severe one. The temperature was higher than in any of the other cases, being 110½° F. No man, be he ever so robust, can long endure a temperature of 110½° F. Yet this one soon recovered entirely and without any sequelæ.

If a case be advanced to collapse, depressing measures are contra-indicated; but before collapse, and during the early stage of insolation, bleeding is certainly a warrantable procedure, at least if the effects of the measure in these cases have been properly estimated.

Heavy Bedclothes Objectionable.—A good many people spoil the effect of a good night's rest by the ridiculously heavy bedclothes they use. Old-fashioned cotton quilts, or modern Marsala ones, are very heavy and of no use, as a thin covering to protect blankets from the dirt is all that is really necessary. Bedclothes should be like body clothing, light and warm. Many a bad sleeper would do well to see whether his coverings are not at the bottom of his restless nights.—*Hospital.*

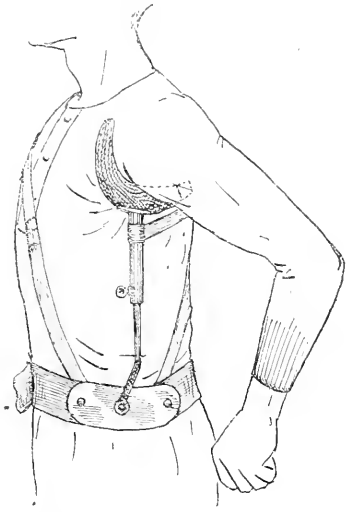
A NEW APPLIANCE FOR THE TREATMENT OF FRACTURE OF THE CLAVICLE.

By W. H. CURTIS, M.D.,

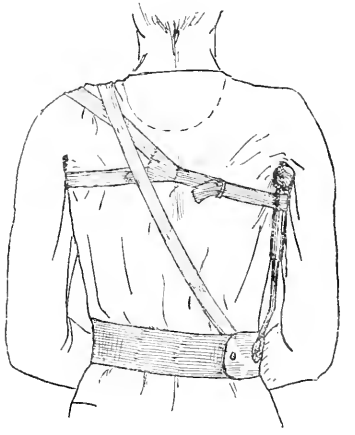
WILMINGTON, ILL.

I herewith submit to the medical profession an appliance for the treatment of fracture of the clavicle, which in my hands has given better satisfaction than any other device that I have ever used.

The accompanying cuts illustrate its construction and application sufficiently well without an extended description.



The crutch-head is of wood, mounted on a round extension-bar of steel, and is controlled by a set screw, which renders it applicable to either side. The lower end of the extension-bar is attached to the waistband by a pivot-joint, and the proper elevation of the injured shoulder is maintained by a suspensory strap passing over the opposite shoulder.



The shoulder is held back by a strap from the upper end of the extension-bar passing around the opposite shoulder, as shown in the cut, thus doing away with the application of any pressure of dressings upon the injured side.

In the cut, the arm is carried back for the purpose of showing the method of applying the instrument.

I am in the habit of confining the arm at first by a sling, or simply pinning the sleeve to the clothing.

The advantages claimed are, that it fulfils the indications, keeping the shoulder up and back, with the utmost possible comfort. It does away with the discomfort and futility of adhesive straps, may be applied outside the clothing if desired, and after partial union has taken place limited use of the arm may be permitted. It is light, easy of application, does not slip or get out of place, is not at all uncomfortable to wear, and, in short, does the work.

My last patient was a very energetic child of two and one-half years, who wore the appliance for three weeks without a word of protest, and with a perfect result. It may be obtained in two sizes, of Charles Truax & Co., Chicago, Ill.

Clinical Department.

DIPHTHERIA FROM CATS.

By P. C. COLEMAN, M.D.,

COLORADO, TEX.

In a recent editorial in the MEDICAL RECORD it is said: "There seems to be quite strong evidence that there is a natural malady in cats which, when conveyed to man, is diphtheria; also, that there is a disease occurring in cows which gives rise to this peculiar cat-diphtheria when the milk of the infected cow is drank by cats."

After a residence of five years in Western Texas I saw the first case of diphtheria in December, 1888, the case occurring in a child, four years old, and living thirty miles in the country, and in a region so sparsely settled that the nearest neighbor lived six miles away. The child had not been in contact with other children for months, and yet developed a violent case of diphtheria, which came very near being fatal, and which was followed by paralysis six weeks after recovery. The other members of the family contracted the disease from the child.

I was puzzled to account for the origin of this case for a long time. The child lived at an elevation of two thousand feet above the sea, in a dry atmosphere, was almost continuously isolated, far from any source of contagion, and rarely ever saw other children. The father of the child asked me, some time afterward, if children ever contracted diphtheria from cats, and stated that two kittens died from some disease which he believed to be similar to the disease the child suffered from, and that he believed the kittens communicated the disease, as the child nursed them almost constantly, and had often been noticed kissing them. I am confident this case was communicated by the cats. I reported it in full at the time, but could not account for its origin, as the father had not then spoken of the cats being affected.

RARE CASE OF ATRESIA VAGINA.

By R. ELLIS, M.D.,

DANBURY, CONN.

Mrs. - , aged seventeen, first suffered molimen menstruale at sixteen, when she was surprised to find that no discharge appeared, though suffering severe pain. Believing that all would be well in time, she suffered until after her marriage, a few months ago, when she presented herself, complaining of severe menstrual pain, absence of discharge, and inability to satisfactorily worship the hymeneal goddess.

The examination disclosed the vulva of a girl of twelve, with an imperforate hymen of dense connective tissue, which, from its elasticity, could be forced back a distance of three inches; a small speculum, unless firmly held, was ejected with considerable force. No fluctuating sac or uterus could be made out by bimanual examination, though the patient stated that during menstrual pain, usually lasting four or five days, she could feel swellings over the Fallopian tubes.

When seen during her monthly sickness, she suffered so severely as to require hypodermics of morphia, which she confessed she had taken before. At this time no swelling or fluctuating sac could be discovered. An operation was advised in order to more accurately determine her condition. The hymen, dense and resisting, was cut through with difficulty, when there was found entire absence of the vagina, the space being filled with spongy areolar tissue; no uterus, sac, or enlarged Fallopian tubes could be made out.

In order to form an artificial vagina, the areolar tissue was cut and torn backward for a distance of three or four inches, when the spongy tissue retracted as deeply as one could insert the index and middle fingers; a glass plug was left *in situ*, and the patient had the satisfaction of possessing a respectable artificial vagina, which, however, is sure to contract somewhat.

From the severe menstrual pain, and from the patient's feelings, it seems probable that she possesses a rudimentary uterus, if any, with normal ovaries and Fallopian tubes; probably her severe pain is due to distended Fallopian tubes resulting from a rudimentary uterus, though neither uterus nor tubes can be made out.

The only relief for her suffering seems to be removal of both ovaries, for where the uterus and vagina do not exist, the case is hopeless unless this is done. In this case ovariotomy will relieve the severe pain and avoid the dangers from ruptured tubes, peritonitis, and pelvic hæmatocele, which may occur at any time.

TREATMENT OF SOFT CHANCRES.

By THEO. G. DAVIS, M.D.,

BRIDGETON, N. J.

Cauterization and curettage are painful and unnecessary. Twice daily the sore is washed with pure warm water, then solution of hydrogen peroxide is dropped upon it until bubbles of gas cease. The sore is then dried with absorbent cotton and dusted with a powder composed as follows:

℞. Bismuth subnit.,
P. cinch. flava ..... āā ʒij.
Calomel..... ʒj.
M.

This is painless and odorless, and has proved entirely satisfactory to patients and to myself during the past four years.

EPISPADIAS OF FEMALE URETHRA SITUATED IN A BIFID CLITORIS.

By CLARENDON RUTHERFORD, M.D.,

PROFESSOR OF ANATOMY, COLLEGE OF PHYSICIANS AND SURGEONS, CHICAGO, ILL.

Recently I was called to deliver a woman who was taken with labor pains while attending the funeral of her husband. The water broke, and she was driven hurriedly home. On being told that no urine had been passed in three days, I attempted to pass a catheter under the clothes, but failing, on inspection I found the meatus situated on the proximal or superior side of the clitoris and in a cleft between its crura. The crura of the clitoris, on its upper surface, were separate, the fibrous septum being deficient. The clitoris was of normal length, and its free extremity was bifid for about one-eighth of an inch. The external opening of the urethra was like a tough or shallow groove between the crura—epispadias. The urethra passed below the symphysis of the pubis. There was no defective development of the pubic bones or adjacent parts.

Progress of Medical Science.

Acute Obstructive Diseases of the Lungs.—To the October number of the *American Journal of the Medical Sciences* Dr. A. H. Smith contributes a paper on this subject. He says that whenever there is obstruction of the pulmonary circulation, the labor of the right heart is necessarily increased. In proportion to its inability to overcome the obstruction there will be an accumulation of blood in the venous system. Excess of blood in the veins implies deficiency in the arteries, and hence this class of affections is characterized by an unequal division of the blood between the venous circulation and the arterial. This condition has extremely important consequences, especially in acute pulmonary affections. In these we study the pulse with the greatest solicitude to judge how the heart, as we say, is supporting the struggle. But the arterial pulse gives no indication of the immediate peril, for it is not the left heart that is bearing the brunt of the battle. The pulse tells its story only at second-hand. It may be small and weak, but it is chiefly because the left heart does not receive enough blood from the lungs to fill its chambers and to distend the arteries. The trouble is not in lack of propelling power so much as in deficiency of blood to be propelled. But if, instead of feeling the radial pulse, we could lay our finger upon the pulmonary artery, we should obtain information vastly more to the point. We should then be able to appreciate the degree of pulmonary obstruction by the fulness of the vessel, and to rate the power of the right ventricle by the force of the arterial beat. And in the relation of these two factors, one to the other, is involved the issue of the case.

Increasing obstruction with decreasing right-heart power means death; decreasing obstruction with sustained right-heart power gives promise of recovery. It is a question with which the left heart, and therefore the radial pulse, has almost nothing to do. For the peril is not from general exhaustion, as, for example, in fever, nor from failure of the heart as a whole, as in some cases of infection, but specifically from tiring out of the *right* heart in its effort to unload the venous circulation through the obstructed vessels of the lungs. Now, while we cannot place our finger upon the pulmonary artery, we can obtain nearly the same information by applying the stethoscope over the pulmonary valve. Now, if we note carefully the sound of the pulmonary valve in, for example, a case of pneumonia, we shall find that at the outset, while the right ventricle is still in vigorous action, this sound is especially clear and sharp, indicating a quick and strong recoil of the pulmonary artery following the ventricular systole. This sharp recoil is due to unusual distention of the vessel, and this, in turn, is due to the resistance which the blood meets in passing through the lungs. If the case is to terminate favorably this accentuation of the pulmonary sound will probably continue through the whole course of the disease, becoming less marked as the obstruction in the lung decreases. But in cases of increasing severity, and with an unfavorable tendency, a time soon comes when not only this accentuation is lost, but the normal intensity of the valve sound is lessened, the sound becoming weaker and weaker, until it ceases to be heard. This means, not that the obstruction has become less, but simply that the muscular power of the right ventricle has become exhausted with the labor exacted of it. The blood is no longer driven into the artery with sufficient force to distend it, and there is not enough recoil to bring the valve-cusps together with an audible sound. When this point is reached the end is not far off. The weakened right heart favors still greater pulmonary obstruction, and this in turn adds to the burden of the right ventricle, thus completing the vicious circle. The struggles of the ventricle become feebler and feebler, while the tension within its cavity constantly increases, as the blood presses into it from behind. At last there comes a moment when the overtaxed muscle cannot summon the energy for another contraction, and its action ceases in diastole.

Dr. Smith makes the following recapitulation of his views: 1. In acute pulmonary obstruction, the danger being from exhaustion of the right heart, the pulse at the wrist does not give reliable indications as to the gravity of the condition. 2. This can be appreciated more correctly by studying the pulmonary circulation by the aid of the pulmonary-valve sound. 3. Marked accentuation of the pulmonary-valve sound indicates a fairly vigorous right heart laboring to overcome resistance in the pulmonary circulation. 4. Decrease of a previously existing accentuation, with only a moderate dyspnœa, indicates decrease of pulmonary obstruction. 5. Decrease of accentuation with increase of respiratory distress indicates that the right heart is becoming exhausted. 6. Relief is to be sought: *a*, by regulating the diet in conformity with the diminished power of digestion and sanguification; *b*, by the use of medicines which dilate the arteries and promote transferrence of blood to them from the veins; *c*, by the inhalation of oxygen gas; *d*, by artifical respiration; *e*, by placing ligatures about the extremities in order to retain the blood in them and prevent its return to the heart.

Exfoliation of the Bladder in the Female.—A case of so-called exfoliation of the vesical mucous membrane is described by Dr. Haultain, the subject being a woman aged twenty-seven. The patient suffered from retention of urine, due mainly to the presence of a mass within the bladder, but protruding at the urethra, its measurements being fourteen by seven and a half inches at its broadest diameters, and in thickness a fifth to an eighth of an inch. Microscopical examination showed the substance to possess a truly membranous structure, three layers, a crystalline granular, transverse muscular, and longitudinal muscular tissue being recognizable. At one point, a portion about one and a half inches square exhibited a smooth, white, glistening aspect, and here there were superadded an old and a new connective-tissue layer. On the evidence afforded by careful examination of the membrane, Dr. Haultain maintains that it consists of the entire thickness of the bladder wall in a state of hyaline necrosis, the white part observed in his case consisting of attached peritoneal covering. He insists, therefore, on the inapplicability of the term "exfoliation of mucous membrane" applied to such cases, under which name similar examples to his own have been described by several other writers. The causation of the disease he attributes to circulatory disturbance due to retention of urine, or labor, these being, one or other, the two concomitants of all the cases hitherto recorded.—*Edinburgh Medical Journal.*

Stone in the Uterus.—In the *Indian Medical Gazette*, Dr. Sobha Ram reports the case of a Mahomedan woman, aged fifty, who was brought into the dispensary, complaining of stone in the bladder. For a year she has had some difficulty in passing urine, with burning and pain during micturition. No blood in the urine. Difficulty has been increasing since, so that the pain and burning were continuous, and had reduced the patient so far that she was unable to sit up or walk about. The uterus was found wholly prolapsed and enlarged, this having occurred about twenty-five years back, after the birth of her son. The os uteri was lying about half an inch from the orifice of the urethra. On palpation, the uterus was found to contain some hard substance, and on pressure urine came out of it. It was tried to pass the sound into the bladder, but the effort was unsuccessful on account of the displacement of the urethra, when the small finger was directed into the os uteri and a stone was felt. The opening was dilated, and the stone was extracted from the uterus. The stone weighed one hundred grains. The patient made a good recovery.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

New York, November 1, 1890.

SHOULD MORPHIA AND ATROPIA BE GIVEN BEFORE CHLOROFORM INHALATION?

It has been claimed by several writers that the effects of chloroform inhalation are more quickly produced, and the anæsthetic influences of a given quantity of the drug prolonged, if a dose of morphia be given before the beginning of inhalation. This statement has naturally found its way into standard text-books. Thus Bartholow says, "before the administration of chloroform morphia should be injected hypodermatically, to diminish the dangers of the inhalation, and to secure relief to the after-pain of the surgical operation;" and again, "when this is done a much less quantity of the anæsthetic is needed to induce insensibility, and the stage of narcosis is sufficiently prolonged for ordinary surgical operations without requiring renewed administration of the ether or chloroform."

In *L'Union Médicale*, August 5, 1890, is published a discussion which took place in the Paris Society of Surgery upon a paper treating of the use of hypodermics of morphia and atropia before the inhalation of chloroform. The author of the paper, M. Regnier, was led to try this method in his practice by the recommendation of M. Dastre, who reported favorable results from its use in animals, and of M. Aubert, a surgeon, who stated that narcosis and awaking were both facilitated by the injection of one-fourth grain morphia muriate and one-eighty-fifth grain atropiæ sulphas, fifteen or twenty minutes before the operation, and that inconvenient results were observed but rarely. M. Regnier used this method with a number of patients, until, unfortunately, a fatal accident occurred.

A feeble girl, aged sixteen, was affected with tubercular disease of the bones of the foot, and as the lungs presented but a few râles in the apex of one side, he decided to chisel out the cuboid bone. Half an hour before the operation he gave a hypodermic of one twelfth grain of morphia and one-two-hundred-and-fiftieth grain of atropia. Anæsthesia was easily induced, and not more than from five to seven fluid drachms of chloroform were required for the whole operation, which lasted only a few minutes. About ten minutes after the chloroform had been removed, and while the dressings were being applied, she opened her eyes without speaking, and she was then carried to her ward. Three minutes later, news was brought that she had ceased breathing. Upon reaching her bed he found the respirations very infrequent. They ceased suddenly as the pulse disappeared, although feeble heart-beats were still heard. The pupil then quickly dilated. Protracted artificial respiration seemed, at the end of half an hour, to excite spontaneous respiration, but this soon failed although supplemented by ether injections and other measures. Post-mortem examination showed anæmia of the cerebral hemispheres and medulla oblongata.

Death in this case came on very slowly from chloroform intoxication. It was quite remarkable that life could be prolonged for more than twenty minutes by artificial respiration. It was claimed that the chloroform must have been eliminated slowly, and that the elimination was rendered more slow than it would otherwise be by the influence of the morphia and atropia.

Two members of the society reported that they had observed, in experiments on dogs, that morphia and atropia given before the chloroform produced no reflex phenomena at the beginning, but rendered more grave such complications as appeared at the end. In some cases there was quite protracted and severe dyspnœa. In dogs thus treated very little chloroform was needed; in men more was required. It appeared to be conceded that the method was useful in the laboratory but not in the clinic, as the chances of intoxication were increased.

Another member who had tried the method stated that in male patients nothing worthy of note was usually observed; while in female patients the awaking was much more slow than with chloroform alone. He thought women were more sensitive than men to the influence of atropia. Out of five cases he had lost one patient. The operation was for nephrectomy, and lasted an hour, fifteen fluid drachms of chloroform being used. After a short awakening the respiration began to fail, cyanosis appeared, and in spite of all measures death occurred in an hour and ten minutes.

Another member had used it in fifty or sixty cases. He did not notice any peculiarities, except that certain patients complained of insatiable thirst.

It was suggested, in conclusion, that the better results obtained with dogs might be due to the very large doses of atropia given (in proportion to the body-weight), which would be utterly out of the question in operations upon human beings.

Interesting as are these observations, and salutary as warnings always are regarding the use of dangerous drugs, the experience of surgeons in New York does not bear out the objections urged against this long-tried and well-known method of mixed narcosis. It is true ether is the anæsthetic here, but it is equally true that no accidents have as yet occurred; but, on the contrary, it has been found that anæsthesia can be more safely prolonged with less ether than under other circumstances, and that the patients are in a more comfortable condition after the operation. Particularly is this the case in operations upon the face, throat, and upper air-passages when the proper administration of ether is attended with unusual difficulty.

THE NUBILE AGE AND EARLY MARRIAGE.

THE case of fatal rupture of the vagina in a child-wife, consequent on sexual intercourse with a mature husband, has excited much interest and discussion in India regard-

ing the subject of the nubile age. It is the custom among the natives of India for the girls to be married before menstruation begins, that is to say, in their ninth or tenth year. The marriage is not supposed to be consummated, however, until after the first menstruation, which very seldom appears before the completed age of twelve years. As a matter of fact, however, it frequently happens that no such delay takes place, and a native physician testifies (*Indian Medical Gazette*) that in about twenty per cent. of marriages children are born by wives of twelve or thirteen years of age.

Cases of death from premature sexual intercourse are by no means rare, while the local injuries inflicted are often serious and permanent.

In a paper upon this subject, read by Dr. McLeod before the Calcutta Medical Society, it was stated that puberty was seldom attained by females in India before the age of twelve, and that the age of legal protection ought to be extended from the tenth to the twelfth year. Some of the native physicians brought out the fact that in parts of India, such as the Madras Presidency, and in South Burmah, menstruation did not occur before the age of fourteen or later. This is about the age in England and America, so that climate does not necessarily make a difference at the time of the appearance of this function. It depends apparently more upon race and habits of life.

The question of the harmfulness or otherwise of very early marriages was discussed by Dr. McLeod; but while he urged that general and not sexual maturity should govern the question of marriage, he did not present any absolute evidence of the harmfulness of child-marriages. It is usually stated that such unions tend to produce race degeneration and premature old age. One physician thought that the girls who had children very early were more liable to have consumption. Since the custom of extremely early marriages is a very ancient one in India, facts as to its harmfulness or otherwise ought to be obtainable; and it speaks rather in favor of the Indian practice that the Calcutta Medical Society could say so little against it.

The feeling in European and American society is decidedly that marriage should be delayed till the girl at least has reached the Lycurgan age of twenty. Meanwhile the man waits till he is twenty-five or thirty, and perhaps has multiple attacks of gonorrhœa, with some more serious troubles, which do not in later years sweeten the course of his domestic life.

It happens, therefore, that while late marriages are physiologically more correct, and often, for financial reasons, necessary, yet the social customs and the moral laxity of the day make the man, at least, who marries late not a very healthful partner.

THE DIAGNOSIS OF TUBERCULAR MENINGITIS.

"Tubercular Meningitis, no one will deny, is difficult of diagnosis. There is no other lesion in infant life which creeps in so unsuspectedly, which develops so quietly, and whose fateful growth may place the physician in such awkward attitude. It fails to appear when foretold; more often steals in unlooked for."

With the above statement, which no one will contradict, Dr. W. P. Northrup opened a discussion on the diagnosis of tuberculosis at the last meeting of the American Pediatric Society. The writer, continuing, stated that there were four important symptoms upon which a diagnosis of tubercular meningitis occurring in the first two years of life might be based. These were: Persistent vomiting, irregularity of pulse, irregularity of respiration, and apathy. In the discussion which followed, Dr. Earle denied the special value of these symptoms, particularly in helping to make an early diagnosis. The four things on which he would lay stress were: 1. A protracted initial stage of slight fever and uneasiness; a desire to go from one person to another; a tendency of irregularity of conduct which sometimes lasts ten days. The child does not know what it wants. One moment it is in the nurse's arms, the next in the mother's, then in the father's, and so on; a long prodromal period which indicates that something is coming. 2. A history of some hereditary taint or trauma. Combine such a history with the first symptom, and you have something of value. 3. If, in addition to these, you recognize cerebral vomiting, you will have three symptoms which will give you a very fair idea of what is going to happen. 4. Local spasm.

Dr. Rotch and Dr. Jacobi thought that the symptoms given by Dr. Northrup were those characteristic of the disease as it occurs between the age of two and seven years. Dr. Jacobi referred also to the important symptom of a low or irregular temperature.

Dr. Winters supported the opinions held by Dr. Northrup, and especially insisted upon the importance of long and patient bedside watching of the case. It is evident, from reading the discussion, however, that a ready and sure method of diagnosticating tubercular meningitis has not yet been obtained.

THE LATE SESSION OF THE NEW YORK STATE MEDICAL ASSOCIATION.

Owing in part to superior committee management, the seventh annual meeting of the New York State Medical Association, at Mott Memorial Hall, was much more than an average success. The papers presented were practical, well considered, and interesting. Some were diffuse, and in the future may tax the condensing powers of the editor of the "Transactions," but uneasy listeners were in the minority. The programme was rather crowded, and necessitated the omission of some of the scheduled contributions, which was the fault of the overflowing debates on pet subjects. Time, we presume, will overcome these shortcomings; and, after all, we cannot deem them serious. We must admit that the Association is doing a good work, according to its own notion, and seems to have an ample excuse for its existence. A working society naturally attracts the industrious.

Bequests to Brooklyn Hospitals.—By the will of the late John Ruszito the sum of $5,000, is left to each of the following institutions: Long Island College Hospital, Brooklyn City Hospital, Brooklyn Homœopathic Hospital, Brooklyn Eye and Ear Hospital. The German Hospital of this city also gets $5,000.

News of the Week.

Why Another Dispensary?—The East Side Dispensary is the name of a new institution just incorporated with a formidable staff of practitioners. The aim is said to be to afford free relief to the poor on the East Side of down-town. This district, as is well known, is adequately covered by the Eastern Dispensary, whose new building at the corner of Essex and Broome Streets is now nearly completed. Too many patients receive free treatment, even in this quarter of the town, and what justifies multiplication of institutions we are unable to see.

The Omaha Physicians are agitating the question of securing legislation for the regulation of medical practice. A curious difficulty exists in the fact that the constitution of Nebraska does not provide for the legislative establishment of a State Board of Health. At present, therefore, it is believed that the only possible regulative measure will be the requirement of a medical diploma. This certainly would be a modest enough restriction.

Strychnia as a "Vaccine" against Tetanus.—M. Peyraud, of Libourne, France, announces that he has successfully "vaccinated" rabbits against tetanus by injections of minute quantities of strychnia.

Responsibility of the State for Infectious Fevers.—A citizen will bring suit against the city of Salem to recover damages for a case of typhoid fever alleged to have been caused by the offensive contents of a barn cellar on the adjoining estate. The plaintiff's wife was taken with the fever and is now seriously ill. The attention of the Board of Health has been repeatedly called to this cellar, but the nuisance was not permanently abated until after the outbreak of the disease, when by order of the Board of Health the cellar was filled up.—*Boston Medical and Surgical Journal.*

The Historical Records of the Members of the Association of Acting Assistant Surgeons of the United States Army are about ready for publication. Those who have not forwarded their army medical history are asked to do so at their earliest convenience. From a professional stand-point these records are interesting and very valuable. Undoubtedly there are many Past Acting Assistant Surgeons of the Army who have served during and since the War of the Rebellion who have not yet joined. It is to be hoped that this reminder will bring many to increase our membership. It is also very desirable that anyone having records of deceased Acting Assistant Surgeons should send historical notes, concerning their military medical history to the Recorder, W. Thornton Parker, M.D., Salem, Mass.

Medical Practitioners' Protective Alliance.—It seems as if the Baltimore physicians were becoming a little desperate. One of them, Dr. J. H. DeWolf, sends to the *Medical Age* the following note: "In Baltimore at the present time are ten dispensaries unconnected with medical colleges; five medical colleges, one more to be added soon. Many of the dispensaries are "general," treating enormous numbers of mechanics, tradespeople, as well as many wealthy people. Over $200,000—I believe almost half a million dollars—are annually lost to medical practitioners. Doctor, send your name for membership. No class of toilers reap less harvest than we. United, we can demand and procure our rights by establishing a Medical Practitioners' Protective Alliance, the object of which shall be to maintain organized co-operation among practising physicians for the purpose of protecting physicians from the abuse of dispensaries, of quick-graduating and inferior medical colleges, and to devise means to enhance our financial condition in every honorable way, and derive the incalculable benefit that can only be obtained by combination."

A Successful Case of Cæsarean Section, in which both mother and child were saved, is reported in the *New Zealand Medical Journal*. The operation was performed in the Otago Benevolent Institution, at Dunedin, the operator being Dr. Stenhouse. The patient was allowed to get up on the twenty-first day, "being then as fully well as a woman after a normal confinement." The special feature in the case was the promptitude with which the operation was undertaken.

Accidental Death of a Physician from Chloroform.—Dr. Justus E. Gregory, a well known physician of Brooklyn, was killed on October 25th, by an overdose of chloroform. He had been accustomed to inhale this anæsthetic for the relief of facial neuralgia. On the evening of his death he inhaled a dose of twenty drops on a handkerchief, he felt some relief but called for another dose, and five minutes later was found dead. Dr. Gregory was forty-nine years of age. He had been a surgeon in the army during the war of the rebellion.

War Over a Hospital.—The case of the People of the State of New York against the Woman's Hospital of Brooklyn was recently before Judge Barnard at Poughkeepsie. The action is brought in the name of the People to dissolve and oust the defendants, whom the complaint alleges are usurpers of the office of trustees. A demurrer and complaint were put in by Donohoe, Newcombe & Cardozo. Argued by Calvin Frost in support and by William N. Dykman for the people. The complaint charges the hospital owners with certain irregularities and other abuses and failing to comply with the law in filling annual reports and using the hospital to promote the private interest of the doctors. Case still on.

Uniform Nomenclature in Anatomy.—The establishment of a uniform nomenclature in anatomy, which was taken in hand by German anatomists about a year ago, has now become an international affair; and the committee appointed for the purpose, which has hitherto consisted exclusively of Germans, now numbers three foreign members—namely, Lebouc of Geneva, Cunningham of Edinburgh, and Romiti of Pisa. The expenses of the task are to be borne by the learned corporations of Germany, because the Anatomical Society, which began it, does not possess the necessary funds. The Prussian, Bavarian, and Saxon Academies of Science have contributed 1,500 marks (nearly £75) each, the Academy of Vienna 1,000 guldens (about £85), and the Anatomical Society 1,000 marks (nearly £50). The completion of the work will be entrusted to a commission, presided over by Professor von Kölliker, of Würzburg. The preliminary work is to be done by an anatomist of special qualifications, including the necessary philological attainments.

The Eleventh International Medical Congress at Rome.—Dr. Guido Baccelli, president of the Accademia Medica of Rome, and Professor of Clinical Medicine at the Sapienza, took the chair at a recent meeting of the Società per il Bene Economico di Roma, to consider the means of ensuring the success of the International Medical Congress to be held three years hence in the Eternal City. Among the adjuncts to that Congress it was decided to form an International Exposition of Hygiene in connection with the Sanitary Department of the programme, and, with that object, to appeal to all the leading industrial and professional centres throughout the peninsula to contribute their best and latest additions to the "Armamentarium Hygienicum," so as to place Italy at as great an advantage as possible in the inevitable contrast between her own sanitary work and that of the other Powers represented on the occasion. Florence, which has hitherto led the van in hygienic progress in Italy, has already promised her energetic co-operation, and other cities, like Turin and Milan, are expected to do likewise. Concurrently with the Medical Congress, an International Exposition of the Industries of All Nations is also being organized, so that Rome will be the busy scene of quite a gathering of the peoples, on a scale she has not yet known since she ceased to be mistress of the world. The early summer months, May or the beginning of June, or the early autumn months, the latter half of September or the beginning of October, are likely to be those selected for the Medical Congress—all risk of malaria at either time being improbable.—*The Lancet.*

The Gas Did not Pass Through.—Dr. Senn gave a very interesting demonstration, before the Surgical Section of the Berlin Congress, of the diagnostic use of hydrogen gas in injuries of the abdomen. A dog was brought in, the delivery tube was inserted, and the gas turned on. Then there was a wait of nearly ten minutes, but no gas appeared, as it should, at the mouth, and the repeated application of a lighted match to the animal's muzzle gave no results. Although the theory remained good the experiment seemed to be a failure, until investigation revealed the fact that the tube had been introduced into the vagina. It was shifted, and in about two minutes the gas appeared at the dog's mouth and was lighted.

A Patient at Dr. Schweninger's Sanitarium sends to *The Lancet* the following account of the regimen to which he was subjected in the course of his "cure:" "Rising, 6.30 A.M.: Cold bath and free towel friction over the whole body. 7 A.M.: Staff and dumb-bell exercise for an hour, with frequent rests. 8 A.M.: Rest and gentle exercise. 8.30 A.M.: First breakfast (meat, eggs, or milk). 9 A.M.: Work at the *Zug* apparatus. 9.30 A.M.: Rest and gentle exercise. 10 A.M.: A walk. 10.30 A.M.: Second breakfast (meat or fish, and a glass of white wine). 11 A.M.: Work at the *Ergostat* (a kind of crank) for half an hour. At noon a walk, and at 1 P.M. dinner (meat, vegetables, and fruit *compote*). During the afternoon some additional gymnastic work is done, and at 7 P.M. supper of one dish of meat and fruit *compote* or salad, with a glass of white wine, or, in some cases, beer. Meals, as a rule, are taken without drinking, fluids being only used some time afterward; though in my own instance this rule was not insisted on. In many cases at 4.30 P.M. a slight additional meal is recommended, thus making four meals a day, which in my own case I found impracticable. Weight, strength, and chest-girth are tested weekly. Coffee, tea, soup, shell-fruit (*Hulsenfrüchte*), potatoes, rice, and red wine are, as a rule, prohibited."

The Philadelphia Medico-Chirurgical Hospital.—Owing to the delay in completing the rebuilding of the Medico-Chirurgical Hospital, the managers have been compelled to provide temporary accommodation for their patients. With this object they have transferred the dispensary service to the college building, and have arranged the rooms previously occupied by the dispensaries into wards for surgical and emergency cases. As an annex for medical and convalescent cases, the property on the southeast corner of Seventeenth and Summer Streets has been secured. This building also contains the matron's and nurses' apartments. The two buildings will accommodate thirty-five patients, and, although they have been open but one week, more than half the beds are occupied.

The Medical Examining Board of Tennessee.—The Medical Practice Act of Tennessee, resembling that of New York, has gone into effect; and the State Board of Examiners, containing representatives of regular medicine, homœopathy, and the eclectics, has been appointed. The hydropaths were left out, and Dr. J. F. Woodward, of McMinnville, who is one of that school, has vented his indignation in a picturesque circular, taking the appointing powers to task for the omission.—*Medical News.*

Chloroform and Phthisis.—Dr. Samuel O. L. Potter thinks that he has discovered a cure for tuberculosis in the almost continuous inhalation of chloroform. He says that as a result of some experiments he feels convinced that this bacillus may be destroyed, and its victims saved, by the continued use of chloroform-inhalation, systematically carried on, day by day, by means of suitable apparatus, and with the care necessary to prevent injurious results or accidental poisoning. "There is no need for the anæsthetic action being induced; but the inhalation can be kept up continuously for several hours daily, and maintained short of general anæsthesia."

The Rumors Concerning the Precipitate Departure of Dr. Lassar, the whilom secretary of the Berlin Medical Congress, appear to repose upon a substratum of fact. It is authoritatively asserted when Dr. Lassar received the official intimation of the intention of the Empress to visit the exhibition annexed to the Congress, he hurriedly gave orders that his own exhibit—containing sundry venereal specimens of an uninviting aspect—should be screened off out of deference to the sex of his august visitor. As ill-luck would have it, the Empress, in the course of her listless promenade, spotted this particular exhibit, and with the curiosity which is the dominant feature of the daughter of Eve, peasant and empress alike, she insisted upon its being uncovered. Dr. Lassar, taken aback and nonplussed, stammered out that the objects were not fit subjects for a female, even if empress, to look at—an observation which excited the lady's anger to such a pitch that the unlucky secretary promptly received an invitation to make himself scarce, an injunction which, in an autocrat monarchy, is not to be treated with contempt.—*Hospitals Gazette.*

Virchow at the Institute.—Calling on him at his rooms at the Pathological Institute, one has to wait one's turn behind a screen which hides the Professor from the eye of the interviewer. This gives one a chance of examining his sanctum, which, to an outsider, appears to be a perfect chaos. Beside his desk, which is covered with papers of every description, we notice a small tray with his scanty luncheon, consisting of a small bottle of beer and two sandwiches; he is a most frugal man while at work. The greater part of his room is occupied by a large number of skeletons and skulls, the floor being simply covered with the latter, through which one has almost to wade to the small table on which stand his microscopes and histological instruments. We find here two very old Hartnacks, one furnished with a low and the other with a high power. These are the only microscopes he uses, and lovely lenses these old glasses encased in rusty frames are. Besides we notice a glass of water, a few glass rods, needles, scissors, and a common razor, and his five bottles of acetic acid, sulphuric acid, iodine solution, salt solution, and caustic potash. For he examines almost everything unstained and fresh, and is extremely skilful in cutting sections with his razor He uses no microtome, and at most a piece of amyloid liver into which he squeezes a small piece of tissue, in this way embedding it, if it be too small to cut it with the free hand. He despises even the double knife, and boasts of being able to make a section through the pons as good as any celloidin specimen. On another table we notice a beautiful modern microscope (Seibert) with all the newest improvements, oil-immersion, etc.; but this is under a glass case and serves simply for show, being never used by the Professor. When showing him a histological specimen, it has to be taken to one of the Hartnacks and be described to him. After examining it carefully, he at most may express his pleasure of seeing everything that has been described. He prefers to see an unstained specimen, except in cases of epithelial tumors, for which he allows staining. In his dealings with men as a colleague or teacher, he is exceedingly fair, showing always his zeal for truth and unbiassed justice. At the same time he is very jealous of his own personal rights, but without any boast or pomp, being careful not to infringe on the rights of others. As he himself says, "the right of experience he places over and above any other right; and the conviction that observation on correctly formed questions in each case must give an answer has never tempted him to try the answer before the observation." The best characteristic of his great mind as a man may be formed in a few words quoted from his preface of the "Cellular Pathology:" "I insist on my right, and therefore I also acknowledge the right of others. This is my maxim in life, in politics, in science."—*British Medical Journal.*

State Preliminary Examinations for Medical Students.—Nearly three hundred persons attended the first State preliminary examinations in this city and Brooklyn this fall.

The Hypodermic Use of Mercury.—At the Lyons Medical Society Dr. Augagneur the other day related a singular case, illustrating once more the danger of administering insoluble medicines. A patient, suffering from a mild type of syphilis, was some time since treated with hypodermic injections of huilegrise—blue oil, if you like—a sort of liquid mercurial ointment, made with oil instead of grease. The disease followed its regular course and the patient was dismissed as cured. But ever since he remained liable to frequent ulcerous stomatitis; and about a month ago, having received a blow on the thigh, the place where the injections were performed, he was taken with so severe an attack of stomatitis that he had to go to the Antiquaille Hospital for treatment. There he was found by Dr. Augagneur to have two tumors, from one of which metallic mercury could be drawn by simple puncture and expression. The other tumor had to be extracted, and was found also to contain mercury.—*Therapeutic Gazette.*

Women Graduates in France.—Since 1866 the University of France has conferred two hundred and two degrees on women, chiefly Russians and Roumanians, thirty-five of whom have received the degree of Doctor of Medicine.

Reviews and Notices of Books.

ASTHMA CONSIDERED SPECIALLY IN RELATION TO NASAL DISEASE. By E. SCHMIEGELOW, M.D. 8vo, pp. 90. London: H. K. Lewis. 1890.

THIS little work is not a treatise on asthma, but is an attempt to show how far diseases of the nasal cavity may affect asthmatic attacks. The author deals with the subject in a scientific manner, and does not take the most extreme views.

LEHRBUCH DER ALLGEMEINEN UND SPECIELLEN PATHOLOGISCHEN ANATOMIE FÜR ÄRZTE UND STUDIRENDE. Von ERNEST ZIEGLER. Zwei Bände. Sechste verbesserte und Theilweise neu bearbeitete Auflage. Erster Band. Allgemeine pathologische Anatomie und Pathogenese. Mit 343 Theils schwarzens, Theils färbigen Abbildungen. Jena: Verlag von Gustav Fischer. 1889.

ZIEGLER'S earlier edition has been translated into English, published by William Wood & Co., and is well known to American readers as perhaps the best of present textbooks on pathological anatomy. The sixth edition is considerably enlarged and brought down to date.

THE DOCTOR IN CANADA. By ROBERT WYNARD POWELL, M.D., Ottawa. 8vo, pp. 342. Ottawa: Gazette Co. 1890.

A COMPENDIOUS directory of Canadian medical legislation, education, hospitals, journals, etc.; of local interest primarily.

LECTURES TO NURSES ON ANTISEPTICS IN SURGERY. By E. STANMORE BISHOP, F.R.C.S.

THIS is the opening manual of the Nursing Record Series published by the Sampson Low Co. (New York: Bromfield & Co.). We find it interesting, but the English books of this nature seem to us too technical for nurses. A list of examination questions is given at the close. We quote one or two: "What were Fehleisen's experiments?" "What is simple aseptic inflammation?" "What do Hueter's experiments prove?" etc. It strikes us that the first and last of these three would be silly questions to ask in their present form—of anyone—especially of a class of nurses. For anyone who has to deliver lectures of this kind, the manual contains many valuable suggestions.

TRANSACTIONS OF THE NEW YORK STATE MEDICAL SOCIETY FOR 1890.

THE proceedings of the eighty-fourth annual session form a handsome volume of 488 pages, and serve as a standard for all similar publications.

Society Reports.

NEW YORK STATE MEDICAL ASSOCIATION.

Seventh Annual Meeting, held at the Mott Memorial Hall, New York, October 22, 23, and 24, 1890.

JOHN G. ORTON, M.D., PRESIDENT, IN THE CHAIR.

The Library.—Dr. Truax, of the Committee of Arrangements, and Dr. Ferguson, of the Council, in reading the reports of these committees, congratulated the Association on the new home for the library, the Mott Memorial Hall, which will also be the place of meeting for the Association.

The Medical Examiners Bill.—In the report of the Council, reference was made to the efforts of the members to have the Governor veto the objectionable medical examiners bill. It was suggested that a committee be appointed to take action in having this bill, or its objectionable features, repealed. A committee of three was appointed later.

The President's Address.—DR. ORTON devoted his address chiefly to the question of medical education in the United States. He did not share the pessimistic view taken by many. Even with some lamentable exceptions of incompetency and discredit to the profession, he still believed that the great majority of graduates of scientific medicine in this country were a credit to themselves, the colleges, and the commoners; while he was not yet willing to say the doors of our medical colleges should be closed to all persons except those wearing literary degrees, yet he trusted the time was near when the equivalent of a literary degree would be demanded of every medical student. He hoped, also, that the day was not distant when not only the minimum qualifications would be indicated, but the maximum attainment would be recognized and honored. Most American medical colleges, he thought, furnished very fair opportunities for obtaining a good medical education. If there was any fault to be found, it was with the general practitioner in taking into his office students naturally incapable or without proper preliminary education. The reader also paid a high tribute to the medical journals in their work of education.

Dwelling upon the subject of sanitation, he forcibly impressed the duty of the profession in educating the public regarding the prevention of disease. He suggested that the medical organizations of the State appoint committees on sanitary science, whose duty it should be to prepare popular articles on the care of the health for the secular press. In this matter this Association should take the initiative step and offer an example worthy of adoption throughout the country.

Miscellaneous Business.—The proposed amendments to the constitution and by-laws bearing on the question of annual dues were adopted.

Prognostics in Medicine.—DR. JOHN CRONYN chose this subject for the address on medicine. In referring to the prognosis of various diseases, both in their natural course and when modified by treatment, the paper covered a rather extensive field. Among the points brought out incidentally were the view that, in diphtheria a true membrane never formed unless the mucous membrane below had first been destroyed; that in nervous diseases the prognosis now was in some instances not so favorable as formerly, because of changed methods of treatment, for instance, in apoplexy, blood-letting formerly saved life in some cases where without it they to-day proved fatal; and the marked value of sarracenia purpurea in small-pox, in preventing pitting and cutting short the attack.

Committee on Hygiene and Public Health.—Acting on the suggestion contained in the President's address resolutions were passed empowering the President to appoint a committee of six, to constitute a Committee on Hygiene and Public Health, which should be charged with (1) "the investigation of questions pertaining to sanitary science, and (2) with the instruction of the people in the proper care of the individual, the household, and the community, by the frequent publication in the secular press and elsewhere of tracts on popular sanitary science."

The Mimiery of Animal Tuberculosis in Vegetable Forms.—DR. E. F. BRUSH, of Mt. Vernon, read the paper. The vegetable forms used for comparison were to be observed in the nut-gall and the phyloxin of the grape-vine. Dr. Leaming's views on the non-causative relation of the bacillus tuberculosis to consumption were quoted. He wished to impress the lesson that our knowledge of tuberculosis was not necessarily complete, as some would appear to suppose, because of the discovery of the bacillus tuberculosis.

A New Method of Surgical Treatment in Certain Forms of Retro-displacements of the Uterus with Adhesion.—DR. A. PALMER DUDLEY in this paper not only described his new operation, but reviewed at some length the advantages or disadvantages of Alexander's and other methods. He had performed the new operation for the first time, December 6, 1889, and three times since. Taking the left tube and ovary, he drew them up, demonstrated that the tube was pervious, tapped small cysts on the ovaries, then dropped the tube and ovary back, and pursued the same course on the right side. He then lifted the uterus as high as possible, denuded its anterior wall of peritoneum, taking care not to go too near the bladder; then each round ligament was brought up, denuded of a portion of peritoneum, and sewed with catgut to the denuded surface of the uterus, the sutures being passed deeply into the uterine tissue to secure against breaking out before union took place. The uterus being dropped, it was found the tension on the round ligaments drew it in the position of anteversion, as was desired. A pessary was not introduced, the uterus had since remained in position, and the patient had been relieved of her symptoms of pain, constipation, etc.

Like good results had also followed in the other cases. The operation, he thought, possessed advantages over hysterorrhaphy and Alexander's method. It corrected displacement by utilizing natural supports; the diaphragmatic action was not interfered with, and the bladder was undisturbed; there was no chance of intestinal adhesion; in case of impregnation the uterus was free to rise naturally. The first patient operated upon became pregnant three months afterward. His experience showed that catgut could be relied upon, and unlike other material, it did not tend to cause a sinus. The cases also showed that ovaries which were sometimes removed in the past, could be spared by tapping the small cysts.

Discussion on Intra-cranial Lesions.—The topic was divided as follows:

Question 1. What are the present means of localizing intra-cranial lesions?

Question 2. What is the nature of the chief intra-cranial lesions (hemorrhage, abscesses, tumors), and how can they be discriminated?

Question 3. What are the indications and contra-indications of operative interference in cases of intra-cranial lesions?

Question 4. What are the best modes of operating in cases of intra-cranial lesions?

into those in which there were pressure symptoms, and those in which there was so called functional disturbance. The first class included cases of abscess, tumor, effusion, and hemorrhage; while among the functional were cases of epilepsy, inveterate headache, insanity, etc. After some reference to symptoms of pressure, location, etc., the author proceeded to consider the technique. Shave the head carefully. This often revealed scars other than that supposed to have been produced by a particular traumatism. An illustrative case was that of a young man who had epileptic attacks following an injury. Three or four scars were revealed after shaving the head, besides the largest one supposed to be the cause of the attacks.

Trephining over this showed nothing abnormal; an instrument was passed between the dura and skull, over the longitudinal sinus, to the situation of the scar on the opposite side; nothing abnormal was found there, while some changes were found under a smaller scar on the side trephined. This patient had been having three to four convulsions a week; he had had scarcely as many in fourteen months since the operation.

Hemorrhage.—The patient should be sitting rather than lying to avoid hemorrhage. Chief reliance had to be placed upon the ligature; veins should be doubly ligated before division.

Hemorrhage from the longitudinal sinus was a most alarming accident.

Victor Horsley had deliberately ligated this in one instance. Oozing from the cut bone was controlled by a putty of wax and vaseline. The opening should be ample, but a very large trephine was not easily managed. On account of danger of shock from a prolonged operation, he always raised the bone and periosteum together.

The electric current was applied to the convolutions to determine their motor function. But the current should not be too strong, nor time wasted in repeated applications.

There was some question as to the value of replacing the piece of bone. He had not seen it cause trouble, and it acted as a protector. If there was danger of intracranial pressure it should not be replaced.

In discussing results, he refrained from using the statistical method. Fractures were excluded. No surgeon would now hesitate to operate where there was abscess of the brain; the patient would die without an operation.

But the difficulty in answering the question when to operate depended largely upon the uncertainty of diagnosis. The same remarks applied largely to tumors.

On the whole, however, the results of surgery for abscess and tumors were encouraging. A considerable number of tumors had been removed, adding a good many years to human life. But a considerable number of patients had died, while in some there had been recurrence. Unsuccessful cases especially should be placed on record. The size of the tumor, whether there was surrounding brain infiltration, central location of the tumor, etc., should receive attention in diagnosis.

Epilepsy.—The most frequent disorder in which the services of the surgeon were sought in brain troubles was epilepsy. In traumatic epilepsy interference had been encouraging. Idiopathic epilepsy had not yielded such favorable results, but we were encouraged to continue [illegible] cases. About twenty-[illegible]

perfect mentality from arrested development gave least hope.

Dr. J. J. Putnam, of Boston, discussed points bearing on localization. It was generally conceded that localized paralysis was a more valuable sign than localized spasms; paralysis indicating a definite lesion, while a convulsion might arise from various causes. The centres controlling the more complicated movements, as of the hands, were more easily set in motion than the others, and might lead one to erroneously locate the lesion in that region. He had reason to believe that the extensor fingers were more easily paralyzed than the flexors. Care should be exercised in locating a lesion by aphasic symptoms; search for other motor disturbances should be made. There were many disturbing elements in estimating the value of temperature measurements. Test the hand-muscles not only as to power, but also as to skill and capacity for continued use. In epilepsy patients were not usually observed long enough after the operation to speak of the permanency of the results. His remarks were based on cases.

Dr. C. K. Mills, of Philadelphia, also discussed the present means of localizing intra-cranial lesions, summarizing our knowledge on the subject. No special addition had been made to that knowledge since a paper published by him nearly two years ago. The motor areas had, perhaps, been a little better subdivided, but this was of little practical value to the surgeon. He had made the point that the angular gyrus itself was not a definite quantity. He believed the areas for cutaneous sensation were different from those of motion, and he thought cases had not in the past been properly selected for operation in many instances. He had witnessed between one and two scores of operations about Philadelphia, and had noticed that too much weight had been attached to the so-called signal symptom in deciding where to operate. The relative normal irritability of the different small motor areas had not yet been well determined. Occasionally, deviation of the eyes and head had been the basis of locating the lesions, but while he believed in cortex areas for the head and eyes, they were liable to mislead because of co-ordinate movements of other parts. A case was cited, an exception to the rule that the sudden onset of the symptoms pointed to hemorrhage, while insidious development indicated tumor or abscess.

In abscess not of traumatic origin the cause was usually aural disease, and one should not attach too much attention to motor symptoms arising later and pointing to a different region. A finer study should yet be made of association tracts. Congenital cases of arrested mental development offered an excellent field for failures. The cerebral fluid tried to make compensation for the cerebral atrophy, and to trephine here destroyed such compensatory pressure, causing death.

Dr. John B. Roberts, of Philadelphia, speaking of the surgery, thought that in abscess of the brain in patients with aural disease, one should seek to confirm his diagnosis by trephining the mastoid before proceeding to trephine down upon the brain. The trephine should be frequently sharpened.

Dr. Frederic S. Dennis, of New York, discussed the second question. The chief intra-cranial lesions were hemorrhage, pus, bone and foreign body, tumors, softening, embolus, and thrombus. The symptoms distinguishing these from one another received attention.

The period of hemorrhage varied from a few moments to several hours, depending upon the size of the vessel and situation. If the vessel was small the symptoms came on gradually, if large, rapidly, and were more pronounced. After clot formed the general features in both cases were identical. If the location were in the motor region and the hemorrhage small, there would be muscular twitchings; if large, there would be paralysis. If the hemorrhage was subdural or epidural the clot would not to absorbed, and surgical interference was called for. Further points in diagnosis were given.

fingers in the right [illegible]
movement of this extremity, and next day the right lower extremity was involved. Dr. Bryant first saw the patient July 1st. Some improvement up to July 10th; but improvement then ceasing, the wound was reopened. An opening in the centre led to a small cavity containing pus. Little improvement followed. On the 25th, beginning facial paralysis; the 26th, affection of speech. From this date until August 14th, loss of power slowly increased, but the pulse, temperature, and respirations presented nothing suggestive of brain disease. Between August 12th and 14th the patient became completely aphasic, and had complete hemiplegia of right side of body. A final operation was performed with the belief that the patient was suffering from advancing cerebral abscess. The brain-substance bulged, was intact, aspiration with a fair-sized needle did not reveal pus or softened brain matter. But free incision directly downward with knife, along which a groove director was passed to the depth of an inch, allowed the escape of softened brain-matter and purulent-looking fluid in small amount. More escaped on enlarging the opening. The patient died four days afterward, unrelieved. Autopsy showed a sinus-like cavity, corresponding to the entire length of the ascending frontal and parietal convolutions, extending into the brain to the roof of the left lateral ventricle, but not communicating with it.

Obscure Fracture of the Skull, with Extensive Epidural Clot above the Molar Tract; Exploration; Death.—The case illustrated, 1, the fact that an extensive tissure could begin at some distance from the seat of the violence causing it, and that its existence might remain unrecognized without an extended exploration; 2, that extensive and fatal vascular complications might be caused at a considerable distance from the seat of an apparently innocent injury of the scalp or skull; 3, that when paralysis involving the motor areas of the brain followed an apparently trivial injury of the head, an operation at the seat of the areas was indicated for the purpose of exploration alone; 4, that the removal of a compressed brain-clot was not necessarily followed by improvement of the symptoms of compression, and if the brain do not soon resume the normal relation with the skull, death would ensue as a result.

Compound Depressed Fracture of the Skull, with Aphasia.—This case occurred in a man who became aphasic immediately after being struck in the temporal region with a bottle. Examination disclosed a small compound, depressed fracture of the skull, located near the lower end of the fissure of Rolando. On elevating the depressed bone all aphasic symptoms disappeared.

Dr. Bryant also related a case of operation for gliomatous tumor. The tumor being central, it was not found. The patient died soon after the operation.

Cerebral Contusion.—Dr. Charles Phelps read a paper on this phase of the subject. The brain contusion might take place at the seat of external injury, or on the opposite side, or somewhere between. Contusion by contre-coup had received little attention in medical literature since the publication of Holmes's "Surgery." That it was important and frequent, he had been enabled to demonstrate by several post mortem specimens, as well as by subjects. In one specimen the blow had caused complete separation at the temporal, sphenoidal, and parietal juncture on one side, yet on that side the brain showed no injury; while at a corresponding point on the opposite side was an extensive contusion.

There might be no external sign of injury where contusions of the brain existed, producing symptoms mistaken for alcoholism. He cited such a case. The mistake was commonly made by the police of regarding patients as under the influence of alcohol when suffering from cerebral contusion. The two conditions were likely also to co-exist. In a case at St. Vincent's, in 1880, a man died eighteen days after injury to the occipital region; autopsy showed an abscess in the cerebrum some ways distant and interior. An early diagnosis in such cases was often obscure, if not impossible. There had been cases of severe contusion without concussion. He gave the following conclusions: 1, Cerebral contusion may be either direct or by contre-coup, and may be either limited, diffuse, or attended by hemorrhage upon the surface of the brain; 2, the superficial hemorrhagic form may cause early death by compression; 3, the limited or diffuse form may cause early death through consecutive general hyperæmia; 4, the symptoms then resemble those of alcoholic intoxication, for which it is usually mistaken; 5, the limited or diffuse forms may cause death at a later period by the formation of abscess; 6, contusion of the brain, with the possible exception of cranial fracture, is in general the most frequent cause of death in injuries of the head as a class.

What are the Immediate, and also the Remote, Results of Operative Treatment in Cases of Intracranial Lesions?—Dr. Thomas H. Manley, in considering this question, divided intra-cranial lesions into extrinsic and intrinsic, the first arising from violence or mechanical influences, the latter from pathological changes within the skull. Cephalic lesions, attributable to trauma, were commonly of compound nature, being associated with contusion, laceration, or puncture of the scalp, with fracture or depression. Conditions following cranial injuries, the patient surviving, had reference to, 1, shock; 2, laceration of brain-substance; 3, hemorrhage; 4, inflammation; 5, purulent formation; 6, localized ulceration, breaking down, or softening.

The utility of operative interference depended upon a multiplicity of circumstances. In a general way it might be stated that fractured or depressed bone of the skull could, when necessary, be expeditiously dealt with by the trephine; yet there were many occasions when the use of the trephine was attended with danger and difficulty. He had had a case in which, when trephining for a depressed fracture close to the torcula Herophili, after removing a disk and slowly clearing away some crushed fragments, blood suddenly gushed forth, and almost at once the patient was dead.

When a sterilized piece of skull-bone formed adhesions with adjacent parts in an adult, he was confident the

Inflammation.—While sepsis could be avoided, yet in many unfavorable cases it was almost impossible to avoid erysipelas, meningitis, and some other forms of inflammation. He had found trephining in the presence of meningitis totally useless. Meningitis was very prone to develop after trephining in children.

Pus.—This, when it formed, did so in an insidious manner.

The Anæsthetic.—The influence of this in brain surgery was more for evil than in operations on other parts. It caused marked congestion of the brain, as indicated by protrusion. This perhaps would account for the marked tendency to hemorrhage in cerebral surgery. The author concluded that greater conservatism was called for in surgery of the brain.

Hypnotism.—Dr. H. Ernst Schmidt treated this subject in a historical way, and then related some cases in his practice which had forcibly impressed upon him the value of hypnotism in certain cases.

Retention of Urine from Prostatic Obstruction in Elderly Men.—Dr. J. W. S. Gouley read an extended paper on this subject. A common cause of impediment to urination in elderly men was enlargement of the prostate, but it was only when the prostate was unequally enlarged that it so acted. The following forms of unequal enlargement obstructing the urethro-vesical orifice need in this paper be named: 1, General enlargement with excessive development of the posterior third of the lower isthmus; 2, enlargement of the posterior third of the lower isthmus without apparent increase in the rest of the prostate; 3, enlargement of one lobe which encroached upon the opposite lobe, obstructing the prostatic urethra; 4, unequal enlargement of both lobes, rendering the prostatic urethra tortuous; 5, multiple intra-urethral tumors; 6, intravesical enlargement of one lobe. The alterations of structure differed somewhat in their component elements. After discussing the symptoms, the means of diagnosis of the several forms of enlargement, especially of four, were pointed out.

Acute retention occurred among elderly men with incontinence as well as among those who had no hindrance. To temporize or rely wholly upon medicaments in its management was to place the life of the patient in great jeopardy. Select the catheter best suited to the case and introduce it. If called during the first twenty-four hours the bladder may be emptied at one sitting of three-quarters of an hour; but if on the second day, draw off only a third, and a little more than is secreted every two or three hours, emptying the viscus in a day or two. Special emphasis was placed on not drawing off too much at one sitting in older cases. The after-treatment should accord with the individual case, but never allow the bladder to again become over-distended. Irrigate the bladder once daily with warm boracic acid solution, three grains to the ounce, with the addition of one fourth of peroxide of hydrogen solution. Chronic retention was also considered, and suitable catheters described.

Dr. E. M. Moore emphasized the necessity of not drawing too much urine at one time, and Dr. J. A. Wyeth spoke of removal of the obstruction by suprapubic cystotomy.

The Therapeutics of Exophthalmic Goitre.—Dr. E.

Double Congenital Dislocation of the Hip-joint.—Dr. W. C. Wile, of Connecticut, presented photographs of a girl, aged ten years, who had come under his observation two months ago, when he found double congenital dislocation of the hip-joint with double lateral curvature of the spine. Double congenital dislocation of the hip-joint was very rarely met with, and the treatment had been of little success.

Dr. L. A. Sayre objected to the use of the term dislocation in these cases, the proper one was displacement; for there could be no dislocation when in the first place there had not been a formed joint permitting of location.

The History of Ligature of Arteries for Aneurism.—Dr. Stephen Smith chose this subject for the address on surgery. He divided the history into three periods, the first up to 1788, the second from that date to 1868, the third since 1868, when Lister showed that ligation of an artery by animal ligature left the artery stronger at the point of ligation, while before, in the use of ordinary ligature, the danger was in secondary hemorrhage.

A Study of One Hundred Cases of Hernia.—Dr. Milliken, author of the paper, stated that 3,058 cases of hernia had been treated at the Hospital for the Ruptured and Crippled during 1889. Of these fully two hundred were complicated by adhesion, incarceration, or strangulation. His studies were based on one hundred of the two hundred. Of the one hundred cases, forty-one were inguinal (twenty four right, sixteen left, one double); thirty-eight femoral (twenty-eight right, nine left, two double); twenty-one umbilical. Considering the relative frequency of inguinal hernia, one might expect to find more cases of adherent hernia. This, he thought, could be accounted for by the disinclination of women, in whom femoral hernia occurred oftenest, to be examined; allowing the hernia, in the absence of a diagnosis, to go on and set up a slow inflammatory process. Only four out of the thirty-eight femoral cases were in males. One occurred under one year of age.

Diagnosis.—First, examine the patient in the upright position, and get a thorough history as to duration and acuteness of the symptoms (in irreducible or incarcerated hernia). To differentiate between omentum and thick sac was often difficult. Encysted hydrocele of the cord might be distinguished by aspiration, and when the sac was not distended a certain thrill was produced when it slipped through the fingers. A small amount of omentum suggested fine bits of fat, just appreciably nodular when passed between the fingers. Enlarged inguinal glands might simulate hernia.

The Spica.—The most commendable feature of this was that it permitted any desired amount of pressure without producing such inconvenience as to necessitate its removal by the patient, resulting in return of the hernia. If any benefit was to result from this treatment, it could usually be obtained in four weeks. Thirty-five cases had been treated by pad and spica, seven of which

were completely reduced, twenty able to wear a truss with comfort, six had an operation.

Regarding umbilical hernia, all the twenty-one cases wore a belt, but one failed to be made comfortable.

Taxis.—Simple taxis, or taxis combined with rest in bed, and hot bath and hot fomentations, succeeded, without an anæsthetic, except in one case. Daily manipulation of the adherent hernia, even after months had passed, would sometimes prove successful. An operation was performed in fifteen cases, in five by the speaker. In eight cases an operation was advised and refused.

Discussion on Obstetrics.—Dr. S. B. Wylie McLeod read a paper, propounding the following questions, which were further discussed in papers by other members:

Question 1. How may the present prophylactic measures in obstetrics be more extended and applied?

Question 2. Is the present technique, in the management of labor and convalescence, in accordance with sound physiology?

Question 3. To what extent have the surgical means of treatment of labor complications been successful, or should these complications and the process of repair have been more generally left to nature?

Question 4. What influence would a more advanced obstetric science have on the biological and social condition of the race?

Prophylaxis.—Dr. Ira B. Read, in discussing the first question and prophylaxis, presented in a humorous manner what the microbic and antiseptic theories would lead to if some extremists could mould obstetric practice. The author, however, advocated strict cleanliness on the part of physician and patient, and use of douche and bichloride only when the lochia showed odor.

Dr. William McCollom, directing his remarks principally to the second question, said the advantage of present methods over the past was shown by the fact that the mortality in lying-in hospitals had become less even than in private practice. Statistics, however, still showed a maternal mortality in Germany of one in 144 confinements. By way of prophylaxis, every woman should abandon the corset with her first knowledge that conception had taken place, should strengthen the abdominal muscles by exercise; attention should be given the alimentary canal, and the urine be examined occasionally. When warned of labor she should take a bath, which effected both cleanliness and quieted the nervous system. The medical attendant should wash his hands in bichloride, have antiseptic instruments, etc. He thought it best to disinfect the genital tract after parturition.

Dr. George T. Harrison discussed the second question. Since the doctrine of the potency of micro-organisms in causing sepsis had attained to general recognition, the conduct of labor and the puerperal state had undergone a radical change, and now we might confidently assert our mastery over the greatest scourge of woman, puerperal fever, by a strict observance of asepsis. If this were true, as it undoubtedly was, then the responsibility of the accoucheur assumed fearful proportions if a fault in his technique allowed the development of this dread disease; and such fault must necessarily involve sins against physiological processes, for normal labor excluded infection. He drew the lesson that internal examinations should be limited, external examination being substituted to a far greater degree than was at present practised. He disagreed entirely with those who taught the doctrine of auto-infection. The genital secretions in the healthy woman were aseptic. He deprecated injections both before and after normal labor. It was seldom necessary to interfere in the last stage of labor, even by the Credé method. Wait for the placenta to be detached by the physiological process. When, however, that had been accomplished he did not think we should wait longer, but should proceed to remove it from the vagina. Credé's method was employed only when there was some obstacle to the expulsion of the placenta from the uterine cavity.

The reader pointed out the potent effect of the continuous dorsal position, and distended bladder and rectum, in the production of backward displacement.

Dr. T. J. Gillicuddy, in discussing the third question said, every case must be treated according to its own merits. No matter how long the woman was in labor, there was no necessity for interference unless she or the infant was in danger. The attendant should not be influenced to interfere for want of time. Wait and send in a larger bill. Severe lacerations should be sutured immediately; others were better let alone.

Dr. A. P. Dudley, in some verbal remarks, showed the advantages in certain cases, now and usually given over to craniotomy, of Cæsarean section or modified operation. The present large mortality from these operations was due to postponement until the patient had become exhausted. He believed in primary operation for tears, and would include even small lesions of the genital tract, making use of catgut suture. He made it a custom to thoroughly examine the parturient tract after delivery.

Dr. W. H. Robb gave a study of some of the causes of a large mortality in the parturient woman. Criminal abortion was alarmingly common, and often resulted in invalidism or death. Other cases in which there was a high death rate were placenta prævia, post-partum hemorrhage, puerperal eclampsia, deformity of the pelvis, etc. Some statistics were given. He believed in the immediate repair of injuries.

Dr. Alfred L. Carroll discussed the fourth question from a statistical standpoint. Taking the average of all the data which he had been able to obtain, the number of dead or dying fœtuses at birth in a million was sixty-six thousand, or one in fifteen. In addition there would be about fifty-eight hundred non-viable children. To what extent this loss of infant life might be reduced was a mere matter of surmise, but in its reduction obstetric science and hygiene must work together. Of the effects of dystocia on the later life of the child, little could be learned. None could doubt, however, that the morbidity from this source was very great. It would not be unreasonable, perhaps, to assume that at least half of the deaths under one month were attributable to accidents in parturition, and that a large residuum of those occurring in the first year had a similar origin.

The maternal mortality from childbirth had been variously given as from one in two hundred to one in five hundred and sixteen.

Regarding social conditions he would have little to say beyond expressing the belief that misery rather than midwifery was responsible for most of the degradation which blotted our vaunted civilization. It might be that in some cases such misery was the outcome of physical disability dating from birth or parturition, but in more instances it was the result of acquired vicious habits. As a "glittering generality," it might be asserted that every obstetric advance which saved mothers from invalidism, and children from incapacity for future effort, must promote the social condition of the race; but politico-economic rules, and the inexorable operation of natural laws, would probably always overshadow in this respect the influence of medical science, or even of Congressional legislation.

Address on Obstetrics.—Dr. Carlton C. Frederick reviewed the subjects in this department of medicine which had received chief attention the past year. Among those subjects were the frequency of sterility due to gonorrhœa; management of retained membranes in incomplete abortion (they should be removed); chronic nephritis as an indication for inducing premature labor (women with chronic nephritis should avoid conception); the possibility of ovarian pregnancy had been shown by Leopold and others; electricity in extra-uterine pregnancy; version; accidents to the ureters during labor, to which Dr. Skene had called attention; Credé's method; relief of pains of labor by anæsthetics; indications for premature labor; craniotomy or Cæsarean section in contracted pelves; aseptic midwifery.

Address on the Medicine of the Classics.—Hon. Charles H. Truax, LL.D., of New York, read a humorous and instructive paper on this subject, which elicited applause and a vote of thanks.

Expert Medical Testimony, of the physician as a witness, formed the title of a paper read by Dr. Martin Cavana. Cases were cited by which it was shown that the physician was likely to be placed in a bad light before judge and jury, if he professed to know too much or failed to impress upon them his honesty and impartiality while exercising the wisdom of the serpent in replying to the questions of the wily cross-examiner.

Some Observations on Bone and Skin Grafting.—Dr. Benjamin M. Ricketts, of Ohio, based his remarks upon a considerable number of experiments which he had carried on in the transplantation of bone, skin, etc., in animals, and to some extent in man. His remarks were directed principally to three questions: 1, When and how skin should be grafted upon raw surfaces caused by injury or removal of malignant or non-malignant growths; 2, how and when may bones be restored; 3, should fragments of fractured bone be permanently removed except in amputation?

It had been demonstrated that almost any kind of tissue could be transplanted from animal or man on like tissue. He was satisfied that sponge-grafts hastened cicatrization of tegumentary wounds, and that the prepuce of boys was one of the most satisfactory of all skin-grafts. He preferred grafts of triangular shape or with ragged edges, as they were less likely to curl. Enough had been accomplished to show the practicability of transplanting the bones of animals to man. He was satisfied that it was impossible to graft bone on other tissue than bone, or tissue of epithelial structure on tissue of other nature. Ivory being of epithelial structure, could be transplanted on to bone, or on the cock's comb.

Bone Intolerance.—Dr. Thomas Manley, in discussing the paper, said his experience with fractures showed great intolerance of bone, especially of sound bone, to surgical interference.

Leprosy.—Dr. Joseph C. Greene read the paper, which treated of distribution, etiology, forms, and referred to treatment. The distribution was shown by a map. He accepted the view that the disease was contagious, due to the bacillus lepra, that it was hard to stamp out when it once gained access to a country, and thought there should be strict quarantine. It ran a fatal course usually in from ten to twenty years, the tubercular form usually in ten years, but in the Sandwich Islands in three to five years. The committee under the auspices of the Prince of Wales was now likely to throw light upon the etiology and treatment.

The Use and Neglect of Blood-letting.—Dr. Homer O. Jewett, the author, remarked that changes in treatment were not always based on sound science, but were due to the tendency of fashion to swing from one extreme to another. This, he thought, was the explanation of the fact that the lancet had fallen almost completely into disuse, unless in the hands of the old physicians. His experience with it had been in about twelve cases of puerperal eclampsia, in pneumonia, and acute inflammation, especially where there was turgescence of the blood-vessels. But he had had no experience in blood-letting for a name instead of a condition. Blood-letting had been employed by him in apoplexy with flushed face, in concussion from traumatism after reaction; he had even cured acute mania by a few bleedings from the temporal artery. He had never regretted the use of the lancet, but had often regretted not using it.

Dr. Darwin Colvin endorsed the paper fully, and emphasized the value of bleeding in puerperal eclampsia.

The Psychical Aspects of Insanity.—Dr. John Shrady, of New York, in his paper upon "The Psychical Aspects of Insanity," reasoned upon the hypothetical basis that the emotions were entities and should be treated as personalities. He maintained that the passions underwent stages of progress, and that by perversion might become dangerous; as, for example, rage might degenerate into murder, and self-complacency might run into the delusion of omniscience. Society, as was taught, appealed to the individuality, whereas in savage life, along with a paternal form of government, the system of communism prevailed. He believed in treatment that the principles of Dr. Chalmers's phrase, to wit, "the expulsive power of a new affection," should be followed out; in other words, that one mood should crowd out another and more dangerous one. This was the father of the idea of substitution, based upon the fact that recreation came from the alternating rest of opposing muscles. Concentration was to be avoided by all means, diversion being the rule. He thought that there was something in the swing of the pendulum, as typified in Ophelia, who was made to sing ribald songs which no modern audience would tolerate, notwithstanding the exquisite music with which they were accompanied. So Hawthorne makes his guilty clergyman yearn to hiss oaths into a sailor's ear.

He also called attention to the intense individuality of the lunatic, who was to be managed especially upon that line. His vanity might be flattered with the excusable purpose of gaining his confidence, so that he might unbosom himself and thus expose the character of his hallucinations. In the study of the subject he had omitted the consideration of all somatic causes, simply because knowledge was to be gained through the medium of words. He did not touch upon medication in its restricted sense, because he believed hygiene and variety of employment or amusements by far the best course.

An Office Battery.—Dr. William H. Robb described the battery employed in his office, which he had selected for its simplicity, range of capacity, and quality of work. The field for electro-therapeutics was becoming constantly wider.

In Abortion, what of the Placenta after the Second Stage?—Dr. Darwin Colvin answered this question in a paper, by the statement, remove it, if uterine contraction will not do it, at once, or as soon as possible after expulsion of the fœtus.

Dr. A. L. Carroll fully concurred in the advice not to leave the patient until the placenta had been removed, and was not aware but what such was the universal teaching until Dr. Colvin showed very plainly that it was not.

Dr. McLeoud also believed in removing the placenta at once, but surprised some in saying he had not seen a death from their retention.

Some Functional Disorders of the Nervous System of Women.—Dr. T. J. McGillicuddy, in this paper, related a number of cases of hystero-epilepsy (he had seen fourteen in all), and also a few of catalepsy. The globulus hystericus was, no doubt, in some instances at least, accompanied by a local congestion and swelling.

Other papers were read by title.

Officers Elected.—*President*, Dr. Stephen Smith, of New York; *Vice-Presidents*, according to districts, Drs. Douglas Ayers, A. T. Van Vranken, J. D. Tripp, and R. J. Merizin; *Council*, Drs. W. D. Gavlock, J. B. Harvie, George Douglas, T. D. Strong, A. L. Carroll; *Secretary*, Dr. E. D. Ferguson, who was also to act as treasurer, the committee making no nomination to fill vacancy left by resignation of Dr. Hinton.

Dangers of Medical Practice in Spain.—A doctor's life is not a happy one in Spain just now, an ignorant and superstitious population having testified to their dislike for sanitary precautions by assassinating three medical officers in the discharge of their duties. Apart from these regrettable and disgraceful occurrences it has been found necessary to send soldiers along with the medical officers on their errand of mercy, though even this precaution does not seem to have secured them against personal violence in many instances.—*Hospital Gazette.*

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

AN ANOMALOUS PUERPERAL CASE—A SUCCESSFUL OPERATION FOR TUBERCULAR DISEASE OF THE HIP—FATAL DYSPNŒA FROM A CASEOUS GLAND IN THE TRACHEA—MYELOID ACROMIAL TUMOR—TRAUMATIC SCIATICA CURED BY OPERATION—SHORT-HAND FOR MEDICAL STUDENTS.

LONDON, October 18, 1890.

THE Obstetrical Society has been the first to commence work for the winter session. At the opening meeting Dr. J. B. Hurry read a paper in which he gave an account of a case of erysipelas occurring in association with labor and presenting some interesting features. The patient was a multipara, aged thirty-five, who, when two weeks from full time, was suddenly attacked with severe headache, shivering, and pains in back and limbs; the skin was hot and the pulse rapid. Delivery occurred suddenly, twelve hours from the onset of these symptoms; there was slight *post-partum* hemorrhage. Two days later on erysipelatous eruption appeared; it was symmetrically placed in front of each ear and pitted on pressure. It spread over most of the face, but there was no sore throat, the temperature was only 102.5° F., and the lochia were normal. As the constitutional symptoms were severe, suckling was discontinued on the fourth day. There was no albuminuria. There were no pelvic symptoms, and the author thought that this had been obviated by applying antiseptic pads to the vulva. He regarded the premature delivery as due to the erysipelas. On the twentieth day the patient was apparently much better, but there was a serous discharge from, and deafness of, the left ear. She was suddenly seized with epileptiform convulsions involving the whole body. There was total loss of consciousness; dilatation of pupils, with no reaction to light, and abolition of conjunctival reflex; slight foaming at the mouth; involuntary passage of urine. Consciousness partly returned in an hour. In the course of the next forty-eight hours twenty-five more fits occurred—becoming at the end less severe. There was no albuminuria. Chloral was given by the rectum and chloroform by inhalation. At the end of forty-eight hours the fits ceased and the patient improved, but complained of headache. There was no impairment of mental power. The discharge from the ear ceased and hearing became normal. On the thirty-fourth day the patient was well. Dr. Hurry thought that the interval of nineteen days between delivery and the outbreak of eclampsia was noteworthy, also the fact of recovery after twenty six fits and the non-occurrence of albuminuria.

Dr. Braxton Hicks remarked that the exact relationship between zymotics, erysipelas, and puerperal fever, so called, had yet to be made out. He thought it most likely that in the bad cases, similar to those seen in hospitals formerly, there were two poisons acting concurrently.

Dr. Herman said that Dr. Hurry took it as established that erysipelas was one of the causes of puerperal fever. Fehleisen had shown that cutaneous was quite different from phlegmonous erysipelas; he had himself no doubt that the latter was one of the diseases included under the term puerperal fever. This was the disease which Virchow had called erysipelas malignum internum. Gusserow had shown that cutaneous erysipelas produced only the same disease in a lying-in as in any other patient. He had himself seen a cutaneous erysipelas in the lying-in woman, and also in the infant, running its ordinary course without producing puerperal fever. He agreed with Dr. Braxton Hicks that cases in which patients appeared to suffer from erysipelas and from septicæmia were cases of mixed infection, in which the poison of both diseases had been received by the patient.

Dr. Boxall drew a distinction between facial, and, as it might be termed, pelvic erysipelas. He thought they were both due to the same cause, and that facial erysipelas might be transmitted to the pelvis either through the tissues or by escaping from the body and being reintroduced into the genital tracts.

Dr. Amand Routh said he thought that, as there was distinct evidence of otitis, the convulsions were due to a transient meningitis secondary to the erysipelas, and were not in any etiological sense puerperal.

Dr. Hurry dissented from Dr. Routh's conclusion, and said he thought the character of the fits, as well as the subsequent history of the patient, pointed to true eclampsia; he regarded the discharge from the ear as due to facial erysipelas.

The first meeting of the Clinical Society for the winter session took place last week. Mr. W. H. Battle read notes of a case (a child of six) in which suppuration of the left hip-joint—believed to be tubercular in origin—was treated operatively with very good results. The joint was opened by means of the anterior (Barker's) incision and a large quantity of pus evacuated. The capsule was swollen and softened. A hole the size of a pea was felt in the anterior aspect of the neck of the femur just below the upper epiphysis. This was scraped out with a sharp spoon (after enlarging the original incision and everting the femur) leaving a mere cylinder of bone to support the head of the femur. The cavity and the interior of the joint were both washed out with chloride of zinc (1 in 30) and perchloride of mercury. Deep catgut sutures were then inserted without any drainage, the wound dressed with sal alembroth gauze and wool, and a long splint applied (with extension). The dressings had to be changed twice within the following week owing to their becoming saturated with urine. Within four weeks from the date of the operation the patient could walk without pain or lameness, and the splint was removed. A large firm swelling which had been present in the hypogastric region finally disappeared, and it was supposed that the repeated manipulations to which it had been subjected had caused its absorption. The patient was subsequently readmitted with typical strumous abscess of the right supracondyloid region. There was a sinus over the position of the lowermost stitch on the front of the left thigh, and the patient appeared neglected, but the movement of the joints continued in every respect perfect.

Mr. Howard Marsh thought the case admirable, but was it pyæmic or tubercular? Mr. R. W. Parker said he thought a good deal of the credit of the case arose from the after-treatment, which—thanks to the method introduced by Mr. Barker—had of recent years been much improved. The same kind of operation, viz., opening, scraping, and sewing up, without a drainage-tube, had been done in many cases at the Shadwell Hospital, and the results had been good in spite of the unfavorable material on which they had to work.

Mr. Battle, in replying, said that the slow course of the disease, the fact that on the opening of any of the abscesses the temperature at once fell to normal, that the child seemed to be scarcely so ill as one usually found a child suffering from pyæmia, the microscopic characters of the growth in the hip, and the later manifestations—especially the abscess of the supracondyloid gland—caused him to regard the disease as tuberculous rather than pyæmic.

Mr. R. W. Parker then read an account of a case of urgent dyspnœa in an infant, aged twelve months, due to a caseous gland which had made its way into the trachea by ulceration. The symptoms were very acute and the case terminated fatally in an hour and a half, although tracheotomy had been performed.

Mr. Bland Sutton then gave an account of a case in which he had removed the acromial half of the right clavicle for myeloid tumor occurring in a woman aged twenty-six. He had, he said, been able to find no other example in modern literature of a myeloid tumor similarly located. He remarked that great care should

be exercised in reporting cases of resection of supposed myeloid tumors, for many endosteal sarcomata mimicked them, and to remove one of the latter and report it as a myeloid tumor would throw discredit on one of the most conservative of surgical operations.

In a second communication to the Society, Mr. Sutton gave particulars of a case of severe sciatica (following upon a dislocation of the left hip, which occurred at sea and could not be reduced for some time) which was cured by cutting down through the gluteus and removing a splinter of bone, fifteen millimetres long, which was found at the edge of the sacro-sciatic foramen in such a position that its point pressed into the nerve when the limb was extended.

With a view of encouraging the study of short-hand among those entering the profession, a voluntary examination in the subject will again be held this month, for which all first-year's students can enter. A prize of five pounds is offered to the most proficient student. A second prize of similar amount is also offered for proficiency in using the art in note-taking, etc.

POST-GRADUATE STUDY ABROAD.

To the Editor of the Medical Record

Sir: I notice in your number of October 4th a paragraph entitled "The Proper Place for Foreign Study," and think I can show that American physicians gravitate to Berlin and Vienna, because they have incomparably better opportunities for study and practice in those cities than they can have in Liverpool, London, or Edinburgh. The writer in the *Medical News*, August 30th, would change his tune if he read the catalogues of the Universities of Berlin and Vienna for the present semestre. Allow me to instance the work performed five days of every week, for six weeks, by an American in Vienna, and many Englishmen and Scotchmen do the same.

From 8 to 9 A.M., Operations on the Eye, Dr. Bergmeister; 9 to 10 A.M., Klinik, Dermatology, Professor Kaposi; 10 to 11 A.M., Laryngology, Professor Schrötter; 11 to 12 A.M., Otology, Professor Politzer; 12 to 1 P.M., Diseases of the Eye, Professor Reuss; 2 to 3 P.M., Skin and Syphilis, Dr. Lustgarten; 3 to 4 P.M., Surgery, Dr. Maydl; 4 to 5 P.M., Diseases of the Bladder and Urethra, Dr. Grünfeld; 5 to 6 P.M., Obstetrical Operations, Drs. Lihotsky and Rosthorn; 6.30 to 9 P.M., Physical Examination and Diagnosis, Dr. Kovacs; besides which he sometimes remained throughout the night at Braun's or Breisky's dormitories, when there was something interesting in obstetrics. A second five weeks were occupied as follows: 7 to 9 A.M., Internal Medicine, Professor Nothnagel; 9 to 10 A.M., Gynecology, Professor Rokitansky; 10 to 11 A.M., Diseases of Children, Professor Monti; 11 to 12 A.M., Diseases of the Urinary Organs, Professor Ultzman (died, 1889); 12 to 1 P.M., Diseases of the Nervous System, Professor Benedikt; 2 to 4 P.M., Pathology, Professor Knudrat; 4 to 5 P.M., Surgical Diagnosis and Operations, Dr. Maydl; 5 to 6 P.M., Diagnosis and Treatment of Diseases of the Ear, Dr. Gomperz; 6 to 7 P.M., Medical Pathology and Therapy, Professor Drasche; 7 to 9 P.M., Gynecology, Operations on the Cadaver, Dr. Erlach.

In this manner one can go on changing every few weeks without intermission, and may also secure good practical courses to fill up part of Saturdays and Sundays.

The professors and assistants are exceedingly obliging and courteous; all speak French and many English, and several courses are given in the latter language, and one who understands a teacher imperfectly can usually obtain enlightenment from a neighbor. Holidays and spare hours can be spent in the laboratories of Professors Obersteiner, Schenk, or Weichselbaum.

Everything is eminently practical, material abundant, and cost reasonable, and one loses no time in going from one to another, as all the courses and clinics are in the General Hospital or the Poliklinik near by.

Professor Widerhoffer gives an excellent course at the Child's Hospital, ten minutes distant, and his able assistant, Dr. Foltanck, also.

A programme may be arranged in advance for a year or more, during which one can hear and see operate Professors Billroth, Albert, Stellwag, Fuchs, Gruber, Kahler, Braun, Chrobak, Stoerk, Schnitzler, Meynert, and many others.

Edinburgh presents better inducements for the American than London, because most of the courses are given at the Royal Infirmary, but the post-graduate course there only lasts five weeks. In London too much time is lost in going from place to place, so that one cannot hope to see as much in the post-graduate course there.

At Paris the same difficulty arises, but Dr. Baratony has been instrumental in organizing a staff of twenty professors for the new Policlinic, and in time the advantages presented will attract more Americans thither.

I should state that at Vienna, besides the regular Semestre Vorlesungen by the professors noted above, at the General Hospital, where each has his own clinic, there are special courses given by their assistants, many of them as able as their masters. Some of these courses continue through the vacations. In surgery there are seven courses; in internal medicine, eight; in laryngoscopy, six; in otology, three; in ophthalmology, five; in dermatology and syphilis, six; in diseases of the nervous system, three; in obstetrics and gynecology, six; in pathology, three; and in diseases of childhood, three; so that a man studying a specialty may spend the whole day in its pursuit and have plenty of material to work on.

At the Vienna Poliklinik many extra courses are given by competent assistants to the professors, and some are given in English. Professors Hebra, Benedict, and Günfeld all speak English well, and the courtesy and consideration shown to Americans by every professor, docent, and assistant is remarkable.

R. F. Macfarlane, M.D.

Albany, N. Y.

ACUTE EPIDEMIC PHARYNGITIS.

To the Editor of the Medical Record.

Sir: After reading in the Record of October 25th, that "grip" is rife again, I would beg to state, that I have been lately obliged to examine several throats for the cause of a violent paroxysmal cough, and found the lower pharynx more or less congested, and in seven cases the capillary vessels standing out in relief, forming a remarkably distinct net-work. This was the only lesion to be positively discovered, and in the beginning, if not sought for, would not be recognized even with the laryngoscope, as in one of my cases, in which, later on, the lesion could be distinctly seen without any instrument. This condition I called simple acute epidemic pharyngitis.

The symptoms observed were as follows: Paroxysmal explosive attacks of coughing. The beginning of an attack would be marked by a sensation of smothering, as if in a smoky room; then followed "a hem!" succeeded by a cough which would increase in severity until the sufferer became almost exhausted, and in one till he "feared he would cough up all the bones of his throat." The night was dreaded on account of the increased liability to attacks. There was little or no expectoration until the patient was getting better, after three or four days, or was effected by sedatives, and then only a little mucus. When the coughing aggravated the inflammation, it seemed to travel toward the larynx and produce hoarseness. When a caustic application was the cause of aggravation it mounted toward the fauces. In a case where such an application was made, the sufferer complained next day of a pricking pain in the throat on swallowing, and examination showed the vessels gorged behind the right posterior pillar of the fauces. The pulse was rapid in all—120 in one, with temperature of 101° F. Tongue had a moderately thick, white fur. Inappetence

and constipation, but rarely vomiting, were the rule. The urine, which in one case held a very heavy brick-dust sediment, was not examined. The highest temperature I found was 101.4° F. Transpiration was easily provoked in all. Nervous symptoms were such in two cases as to render the sufferers completely prostrate. There were headache from coughing and insomnia. One patient complained of pain above the xiphoid cartilage. This was not aggravated by breathing, coughing, or movement, and he had been vomiting, so I attributed it to gastric disturbance. The treatment consisted simply of a sedative internally, and a spray or gargle of chlorate of potash and carbolic acid; or chloride of ammonium 1 to 500, and bichloride of mercury 1 to 5,000. By this means the encroachments were removed in twenty-four hours or less, though the cough in some degree persisted.

A strange fact was observed, that smoking would not at the time provoke a paroxysm. On this subject Flint[1] says, "Simple acute pharyngitis occurs as an epidemic affection, sometimes prevailing greatly and widely. It prevailed to a considerable extent in this city (New York) during the spring of 1864. It resembled influenza, save that the pharyngeal, and not the bronchial, mucous membrane was the seat of the local manifestation."

In the *Buffalo Medical Journal*, vol. xii., p. 718 *et seq.*, will be found a description of the disease as studied by Professor Flint, Dr. Rochester, *et al.*, in 1857.

Yours very truly,

J. J. E. MAHER, M.D.

NEW YORK.

DERMATOLOGICAL INSTRUCTION IN AMERICA—REPLY TO DR. FOX.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In the last issue of the MEDICAL RECORD Dr. George H. Fox calls into question the strict truthfulness of the statement, quoted in your editorial remarks from my address on "Dermatological Instruction in America," viz.: "There is no medical school in this country in which the study of diseases of the skin is obligatory, in none is a knowledge of this important branch of medicine required as a condition of graduation," etc.

Commenting upon the above Dr. Fox says: "In the College of Physicians and Surgeons of this city the study of diseases of the skin is obligatory. No student is allowed to graduate there without passing an examination in this important branch, while the professor in this department is not only allowed but required to conduct this examination, the result of which decides in a measure the student's qualification for a degree."

I should be sorry if my remarks had done injustice to any medical school, especially to such a time-honored institution as that of the College of Physicians and Surgeons. I elsewhere stated in the body of my address "that the College of Physicians and Surgeons of New York has made the concession of allowing a single question relating to skin and venereal diseases to be proposed by the professors in these departments, but this is notoriously insufficient to test the knowledge of the student."

This statement was based upon information relating to the conditions of graduation contained in the "Annual Announcement and Catalogue of the College of Physicians and Surgeons, June, 1890." On page 25, under the section "Examinations" it is stated "that the examination in the topic of 'Clinical Studies' comprises one question in each of the following subjects (including skin and venereal diseases) set by the Clinical Professor thereof." Now, whether "one" question "set" by the Clinical Professor of Skin Diseases constitutes an "examination," in any proper sense of the word, or enables him to judge of the student's knowledge of this important branch, is open to question.

Dr. Fox's assertion that the result of this examination decides, in a measure, the student's qualification for a degree is not borne out by the clause following (page 25), in which it is expressly declared that "candidates are not 'conditioned,' however, in the topic of 'clinical studies.'"

I am, etc.,

PRINCE A. MORROW, M.D.

NEW YORK, October 25, 1890.

[1] Practice, ed. 1881, p. 452.

WHICH WAS THE FIRST POST-GRADUATE SCHOOL IN NEW YORK?

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of October 25th, under the heading of "The London Post-Graduate Course," there occurs: "Six years ago the New York Post-Graduate Medical School was incorporated, and it must be with no little satisfaction that the founders now read of the establishment of the London Post-Graduate Course," etc. "We send our felicitations to the London School, and wish it a like success to that which the parent school here has had."

No doubt the London Faculty will be pleased to receive the felicitations of your paragrapher, for the felicitations of the RECORD are not to be disregarded or despised; but won't you please to remember, when you next send congratulations to London, that there is another school of Clinical Medicine and Surgery in New York City (the same city in which the Post-Graduate School is situated, and in which the MEDICAL RECORD is published), which school was organized in 1881, while the gentlemen who afterward organized the Post-Graduate School were still Professors in the Medical Department of the University of the City of New York, which school was opened in 1882, and has had, up to August, 1890, two thousand two hundred and fifty-five physicians as students (a larger number than any similar institution west of the Atlantic Ocean), and which school is the New York Polyclinic, with a P.[1]

In one of your editorials, p. 408, RECORD of October 7, 1882, it is written: "The most successful polyclinic will entice the greatest number of students, and will lay the foundation for the most successful post-graduate school." Prophetic RECORD! And yet, in sending felicitations to London, you forgot "the most successful post-graduate school" in New York. In the language of the Psalmist, "I will praise thee forever, because thou hast done it!"

SECRETARY.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from October 19 to October 25, 1890.

GLENNAN, J. D., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month, to take effect about the 31st instant. S. O. 146, par. 1, Department of the Missouri, October 23, 1890.

JARVIS, N. S., Assistant Surgeon. Granted leave of absence for one month, on surgeon's certificate of disability. S. O. 107, Department of Arizona, October 14, 1890.

PILCHER, JAMES E., Captain and Assistant Surgeon. By direction of the Secretary of War, granted leave of absence for four months. S. O. 244, par. 12, A. G. O., October 18, 1890.

Official List of Changes in the Medical Corps of the United States Navy for the week ending October 25, 1890.

CORDEIRO, F. J. B., Passed Assistant Surgeon. Detached from the Nipsic, and granted three months' leave of absence.

HEFFENGER, A. C., Passed Assistant Surgeon. Placed on retired list, October 20, 1890.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending October 25, 1890.

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	43	7
Scarlet fever	23	2
Cerebro-spinal meningitis	0	0
Measles	74	5
Diphtheria	63	20
Small-pox	0	0
Varicella	0	0
Pertussis	1	0

The Spleen Vindicated.—So the spleen, which our forefathers looked upon as an unmitigated nuisance and of little or no use to us (and we are inclined to agree with them and throw the liver into the bargain), does some very necessary and highly useful work. The modern scientists would no doubt agree with Pliny, that people who got rid of the spleen by the way of incision or burning with a hot iron would lose their laughing, but their observations have led them to believe that its retention, as an assimilator and constructor of new blood-elements, especially the white blood-globules, which act as runners in bringing health-destroying germs to bay, is preferable to its destruction.—*The Hospital.*

Hints to the Unfortunate.—A few suggestions, culled from accounts in the daily press, of recent cases of accidental death may prove of service to those who are not ingenious enough to think of them for themselves: 1. Mix some coarse flour and strychnine to kill the rats with, then place the mixture in a jar, similar and as near as possible to that containing the family oatmeal. 2. Place some laudanum in an empty medicine bottle, and stand it alongside a bottle of physic on a table by your bedside; take a dose, from the nearest bottle, in the dark; ten chances to one it's the laudanum. 3. Pour some carbolic acid into a beer-bottle, cork it, and put it aside in a cool spot; the next person who comes along with "a mouth on him" will find it a vast improvement on common or ginger beer. 4. Smear a piece of bread with phosphorus paste (Rough on Rats) and leave it in a cupboard well within reach of marauding youngsters; if their lives are injured, you will have no reason to regret the experiment.—*Hospital Gazette.*

Photography at the Morgue.—In the various morgues of this country it has been found necessary to photograph the bodies as soon as practicable. The old method of exposing them on marble tables covered with ice was found very troublesome, and as mortification set in rapidly the object of this exposure was in many cases defeated. Under the new system sixty-seven per cent. of those received last year were identified. Not only the bodies are photographed but all of the clothing and small articles found upon the body. The grave then being numbered to correspond with the photograph renders identification easy. This is a great improvement, and we are glad to know that the poor unfortunates, after a woful and tragic life, are not kept on the threshold of the grave exposed to the curious gaze of the vulgar sensation-seeker.—*Gaillard's Medical Journal.*

Megalocephalia, or Swelled Head.—The *Maryland Medical Journal* discusses editorially the two varieties of this disorder. The congenital variety is so well known that it requires no notice. Concerning the acquired type of the disease, it is said that it affects persons of moderate abilities who have been suddenly, through the influence of friends, raised to positions of eminence and responsibility. It is said that cases are frequently observed among railroad officials or custom-house officers, and that they are occasionally met with in the Health Departments of our cities and States. The brains of the unhappy subjects of this sad complaint were formed and educated for the performance of quiet, unexciting labor in the small trades, and their possessors did well and respectably in such spheres of life. Being suddenly elevated, through politics or similar influences, to posts of great responsibility for which they were in nowise fitted, their brain-cells were unequal to the strain, and various unhealthy forms of thought and action made their appearance. They began to act as if they were bosses, instead of servants, of the public, and as if mere perfunctory performance of their duties rendered them sacred and above criticism. The prognosis in this form is very unfavorable, hopeless in the congenital variety, hopeless in the acquired variety, unless the patient quickly returns to his former sphere and stays there. Apart from this all treatment is useless.

Are Children Happy?—People have a great deal to say about the happiness of childhood, but they are grown up before they say it. For, after all, children have a harder life of it than their elders do. To begin with, there is the constant discipline life gives them in such Scripture measure—the things they want and are forbidden to have; the things they do in ignorance to be punished for without clearly understanding the offence; the imaginative terrors of darkness and evil spirits and unknown powers, to say nothing of an offended Deity who is angry when they eat too much bread and jam. And then there is the school with its hard discipline of having to study Chapter XX. in the big book of learning, which is the Long Division, when their legs are aching to be at Chapter XLI., which is playing "tag" on the village green. And there is their wondering misapprehension of their elders and the vague but awful sense of suffering they have at hearing impending calamities spoken of, which they can apprehend as sharply as their elders, but which they see no earthly means of escaping—the possible death of a dear one, a coming scourge of disease, the loss of money, or the end of the world. And there is—oftener, perhaps, than all else—the sharp grief of being misunderstood; of having their thoughtlessness and ignorance taken for wilful disobedience; of feeling their natural, healthy fearlessness taken for pertness and forwardness; of having, even their very love thrust aside because it is manifested at an inconvenient moment—of finding themselves, in short, in a great big world, where everything is to be learned, and where the only persons who can teach them are most given to bejuggling and bewildering them.—*The Sun.*

The Increase of Insanity in Germany.—The number of lunatics in the asylums of the city of Berlin, which was 1,582 in 1882–83, amounted to 2,528 in 1889. This shows a very large increase in the number of insane persons relatively to the growth of the population. In the period referred to the increase in the population was 22.49 per cent., while the increase in the number of lunatics was 59.79 per cent. The number of insane persons in confinement in the whole German Empire rose between January 1, 1881, and the same date in 1886, from 34,270 to 42,669, being an increase of 24.5 in the five years, as against an increase of 3.6 per cent. in the general population in the same period. The increase of insanity in Berlin has made it necessary that a new public lunatic asylum should be established. The building, which is to accommodate 1,000 patients, will be situated in the easterly suburb of Lichtenberg. The city of Berlin already maintains an asylum with about 1,200 inmates at Dalldorf.

Water a Preservative.—After some forty years of immersion in the waters of the pool of Echoschacht, not far from Hermannstadt, several human bodies have been brought to the surface in a state of perfect preservation.

SOME PRACTICAL CONSIDERATIONS ON THE NATURE AND INDUCTION OF THE HYPNOTIC STATE.[1]

BY J. LEONARD CORNING, M.A., M.D.,

NEW YORK.

CONSULTANT IN NERVOUS DISEASES TO ST. FRANCIS HOSPITAL, JERSEY CITY; THE HACKENSACK HOSPITAL, ETC.

AN immense deal of labor—and most honorable labor it is, too—has been expended in the elucidation of the physiological and pathological questions connected with the nervous system. The literature which has grown out of these efforts is overwhelming both as regards magnitude and complexity; but, what is equally apparent, is the fact that much of this matter is of but temporary importance, if it be not altogether ephemeral. This lack of fixity in theory finds an appropriate counterpart in the mutability which pervades the whole realm of neurotherapy, or at all events the greater part of it. Of late years this state of affairs has been provocative of wide spread discontent in the profession; so that at present there is discernible a strong tendency, among practitioners at least, whatever may be said of the devotees of the laboratory, to lay hold of any procedure which offers a chance, however insignificant, of adding to the curative resources of this important field.

It is this reversion to the practical side of neurology which explains in a measure, I think, the extraordinary interest which medical men are manifesting, and will doubtless continue to manifest, in the question of hypnotism.

Whether hypnotism is to maintain a permanent position among the agencies at our command for alleviating human ailments, and especially those which affect the nervous system, time alone will reveal. For us the fact remains that a mass of data bearing on this question is at hand, and is being added to every day; so that the time cannot be far distant when the profession will be called upon to express itself with somewhat more decision on this important topic. It will, therefore, not be time misspent, I fancy, if medical men at large concern themselves, at least in a general way, with the more salient phases of hypnotism.

It is impossible, in a paper of such brevity, to review the history of those psychical phenomena which are collectively known to us to-day as hypnotism. I shall, therefore, be as brief as possible, confining myself strictly to fundamentals.

To begin the argument, let me state that the old doctrine of Mesmer, the charlatan, that the manifestations of hypnotism are due to a magnetic fluid, all pervasive in character or emanating from the human organism, has been universally discarded by the scientific experts of our day. In its place we have the theory which finds in suggestion the chief, if not the exclusive, cause of the phenomena. Braid, of Manchester, was the first to clearly expound this doctrine (1841). He showed that the hypnotic condition and all cognate phenomena are purely subjective in character and origin, being one and all the outgrowth of an exalted condition of the imagination. Now, this exaggeration of the imaginative faculties, which is so characteristic of hypnotic states, is brought about by the total, or almost total, suppression of those faculties which, under normal circumstances, serve to counteract or hold the imagination in check.

Practically, this suppression of the judgment and will, more particularly the latter, may be attained by causing the subject to direct his whole attention to the contemplation (fixation) of a brilliant object; and, if the latter be so placed as to cause some strain of the upper eyelid, the effect will be all the more certain. The phenomena which may be evoked in this way are, after all, not so difficult to account for, if we but bear in mind that the more developed and untrammelled the imagination, the greater is the sensibility of the subject to all promptings or suggestions, whether the latter originate in his own mind spontaneously or are placed there by others. We see this in healthy imaginative persons every day.

Now, the prolonged fixation of a bright object is fatiguing to the muscular apparatus of the eyelids (especially if the object be placed at some height above the head of the subject); and, besides—what in my judgment is far more important—it is exhausting to the central perceptive mechanism in the brain. Moreover, these two kinds of fatigue are not only direct, but also indirect, promoters of drowsiness, insomuch as they suggest to the subject the thought of sleep. Thus we see that in the very induction of the hypnotic state suggestion is a valuable ally. It only remains to add in this connection, that the intense fixation of the attention, which frees or exalts the imagination sufficiently for the purposes of hypnotic suggestion, may be obtained through any one of the special senses, though certainly not as well by the aid of taste and smell as through sight and hearing. Hence the efficacy of monotous sounds or passes in inducing the hypnotic state, especially if the subject be told that these things produce drowsiness. But, even if nothing on this score be intimated by the operator, the things themselves are sufficiently suggestive of sleep to facilitate the hypnotization of the subject. So much, then, for the principles involved in induction of the hypnotic state. And now, let me offer a few remarks on the various degrees of the hypnotic state, for the latter is capable of wide variations.

Though the classifications presented by different authors have their advantages, I regard the arrangement of the phenomena adopted by Liébault as theoretically commendable, and perhaps, on the whole, as practical as any heretofore proposed.

Classification of the Degrees of Hypnotic Influence, Proposed by Dr. Liébault.—The degrees of hypnotic sleep recognized by Liébault are six in number. The first is characterized by more or less drowsiness; the second by what is termed suggestive catalepsy; the third by rotary automatism; the fourth by the relation of the subject through the sense of hearing, solely to the operator; the fifth by what is known as minor somnambulism; and the sixth by profound somnambulism.

Let me explain at once what is meant by the terms catalepsy and somnambulism, as employed in connection with hypnotism. By catalepsy we mean that condition of the subject in which he is compelled to maintain his limbs in any position in which the operator may place them. In some cases, the mere act of holding the limb in the desired position suggests the idea to the subject that he is to maintain it there; and this suggestion is often forcible enough to cause the limb to be held in

[1] Read by invitation at the joint meeting of the White River, New Hampshire, White Mountain, and Connecticut River Medical Societies, July 31, 1890.

place. Sometimes, however, the mere holding up of the limb is not sufficiently suggestive to bring about this result; and hence we are compelled to resort to the more lucid and forceful expedient of verbal suggestion. We then say to him: "Keep your arm up," "Shut your eyes," "Hold your foot up," etc. These are facts with which all who have devoted any study to the subject of hypnotism are familiar.

And while we are considering this point, let me remark that two kinds of suggestions are possible through the agency of hypnotism: In the one case we may suggest acts to the subject, during the hypnotic state, which are to be realized while he is in that condition; while in the other we may say, "This or that will occur to you," or "You will see or hear this or that" at some future time. The acts and hallucinations which are to take place during the hypnotic state may be suggested to the subject while he is under a minor degree of hypnotic influence; but the post-hypnotic acts and hallucinations, to be successful, must be suggested while he is in that profound condition of hypnotism called somnambulism. And now, let me explain what we mean by this term in its hypnotic sense. By somnambulism we mean that phase of hypnotism which is characterized by complete forgetfulness on awakening of everything which occurred while the subject was asleep.

Let me enumerate a little more fully the phenomena which Liébault has indicated in his excellent classification.

During the first stage of hypnotism, according to Liébault's classification, the subject evinces more or less drowsiness, which condition of lassitude may be evanescent in character, or it may persist for some time. Even when there is no sleep, in the ordinary sense of the word, the eyelids remain closed, and there may be inability to open them, especially if the brow has been touched by the operator in the manipulations incident to the induction of the hypnotic state.

The second stage is characterized by the evolution of cataleptic susceptibility. It is true that the tendency to catalepsy may not be apparent at once. We may place a limb, say the arm, in a given attitude, and, instead of maintaining it, the arm resumes its original position. If, however, we try the same experiment several times, adopting the precaution to support the limb in the intended attitude for a few moments, the latter is often maintained for some time.

All the phenomena are more pronounced in the third stage, and, in addition to the catalepsy, what are known as automatic movements are added. These are nothing more than continuous rhythmical motions, which may be suggested to the patient quite like other acts. Thus we cause his hands to describe circles around each other, and then intimate that he cannot cease the manœuvres; and, sure enough, the motions are continued almost indefinitely, or till the muscles concerned are exhausted. It is a remarkable fact, however, that, while all this is going on, the subject is able to hear and interpret what is said by those about him.

What Liébault calls the fourth degree is nothing more than a slight modification and intensification of the preceding stage. During its supervention, the subject is no longer, strictly speaking, in juxtaposition with his environment. The words of persons about him are not heard, or rather, only those of the operator are perceived.

In the fifth degree we have the inception of somnambulism; that is to say, the memory of the patient for what has taken place while he was under the hypnotic influence is much impaired.

The sixth stage marks the supervention of profound somnambulism. When the subject emerges from this state, he has no recollection whatever of what has taken place during the sleep-like state.

During somnambulism all the more extraordinary phenomena of hypnotism—hallucinations, abolition of sensibility, catalepsy, motor automatism, and hallucinations of the special senses—may be induced by the aid of suggestion.

It is natural that in the presence of such an array of startling facts, physicians of the present day should make the inquiry as to whether hypnotism may not be turned to some account in the management of diseases, and particularly nervous diseases. The question is not a new one, and has been propounded again and again, ever since Mesmer, the charlatan, exercised his unscrupulous powers over an army of confiding dupes.

The most ambitious and recent attempts to revive the use of hypnotism in neuro-therapeutics are those of Liébault, Charcot, Luys, and Bernheim.

Probably many of my hearers are familiar with the utterances of these gentlemen on this question. The limited time at my disposal does not, however, admit of an extended review of their undertakings; and I shall therefore content myself with a brief description of the salient features of Liébault's system, which, be it well understood, embodies the chief advantages of the methods of most or all other advocates of the treatment of disease by hypnotism.

Liébault proceeds, according to his admirer, Dr. Bernheim, as follows: "The patient is put to sleep by means of suggestion, that is, by making the idea of sleep penetrate the mind. The subject being hypnotized, M. Liébault's method consists in affirming in a loud voice the disappearance of his symptoms. We try to make him believe that these symptoms no longer exist, or that they will disappear; that the pain will vanish, that feeling will come back to his limbs, that the muscular strength will increase, and that his appetite will come back. We profit by the special psychical receptivity created by the hypnosis, by the cerebral docility, by the exalted ideo-motor, ideo sensitive, ideo-sensorial reflex activity, in order to provoke useful reflexes, to persuade the brain to do what it can to transform the accepted idea into reality." Such is Bernheim's[1] picturesque description of the method of Liébault.

The next question which naturally suggests itself is: In what class of cases may hypnotism be invoked with a reasonable expectation of accomplishing something for the good of the patient? My reply is that, inasmuch as the effects to be derived from hypnotism are functional, the class of derangements in which it may possibly be applicable must also be functional. And, moreover, as a corollary to what has been said regarding the phenomena evoked by hypnotism, I would state my belief that the legitimate field for the application of therapeutics of this class is in the management of certain nervous diseases of functional origin.

In this conservative statement of the class of cases in which hypnotic suggestion may properly be invoked as a remedial measure, I differ entirely with Bernheim, who believes that the method may also be resorted to with advantage in the treatment of organic diseases. Some of the arguments which he advances in defence of this position are ingenious, I must confess, and this is notably true of the supposed case of cerebral hemorrhage, in which, while a certain number of centrifugal fibres have been destroyed, others are assumed to be intact, but refuse to perform their functions, "being stunned by the shock to the neighboring fibres." Now, it is these "stunned" fibres which Bernheim proposes to revive into activity by resort to hypnotism. Of course, the objection to all this is simply the fact that, in the vast majority of cases of organic trouble, what the physician is most concerned about is not the revival of real or imaginary "stunned" fibres, but rather the arrest of the further growth of the lesion, or its removal with the knife or by the aid of drugs, as in syphilis.

Because we do not by any means always succeed in producing an effect upon an organic lesion by the aid of

[1] Suggestive Therapeutics: A Treatise on the Nature and Uses of Hypnotism. By H. Bernheim, M.D., etc. Translated by Christian A. Herter, M.D. Pp. 206–207. New York and London, 1889.

drugs, is, indeed, rather a reason why we should *not* lay hold upon the less obvious support afforded by mental therapeutics.

Mental impressions, especially those received in the hypnotic state when the imagination is free, or largely free, from the resisting influence of the higher controlling faculties, are doubtless of great potency, but only so in a functional sense. To affirm that the organic process called multiple sclerosis may be retarded through the aid of the suggestions of hypnotism, is not to advance medicine either as an art or a science, but rather to bring it into discredit in both capacities.

In our future investigations in this realm of therapeutics, do not let us seek the impossible; let us rather go slowly about it, attaining—it is barely possible—a little less, but guarding thereby our art from the inroads of the unscrupulous. We have previously considered the principles; let us now examine the practical features connected with the induction of the hypnotic state, or "sleep," as it is often called.

Among those whose acuteness and subtle powers of analysis have enabled them to speak with authority on hypnotism, two phases of opinion are at present discernible. On the one hand, we find a number of observers, prominent among whom are such excellent authorities as Liébault and Bernheim, of Nancy, who believe that suggestion governs a large majority of hypnotic phenomena, and that the appearances, which by some are attributed to physical causes, are entirely psychical in origin. Followers of this school perceive in the strokings and passes often employed in the induction of the hypnotic state, nothing more than the machinery of suggestion—or at least not much more.

On the other hand, we find another company of investigators who, while ready to accord due importance to suggestion, still persist in ascribing the higher manifestations of hypnotism to an inscrutable something, over and above mere suggestion. Some of the most distinguished advocates of this theory are to be found in Paris. Thus we find that among the acute and learned men of France opinion is divided on this important question. There is, however, nothing new in these differences of belief; indeed, the whole history of hypnotism reveals them almost from the beginning—from the days when Mesmer, the charlatan, gave instruction in his grotesque mysteries.

In Bernheim's clinic, at Nancy, patients are hypnotized by requiring them to look fixedly at the operator or his eyes; while their expectancy is aroused by suggestions relating to sleep. "You are going to sleep," "your eyelids are heavy," "you cannot see well," "your eyes are closed," are some of the phrases which may be employed for this purpose.

Donato,[1] of Liège, believes that "the art consists in captivating the mind of the subject, in striking vividly the imagination, in seducing, charming, or subduing it." Hence, in his estimation, "the surest way to affect the imagination of a person, impose upon him a stronger will, consists in working with the rapidity of lightning, without giving him the time to reflect or recover his sang-froid. It is by surprising my subjects that I obtain paralysis, aphony, etc., without even trying to send them to sleep previously."[2]

Following out these ideas to their practical sequence, Donato has adopted several processes which he uses alternately, according to circumstances. "The principal consists in making the patient press his hands strongly on mine. Suddenly I push him backward and I quickly plunge my glance into his eyes. Surprised, he recoils, and immediately the expression of his eyes indicates to me his degree of impressionability. When I find him easily submissive to my influence, I make a circular movement with the head and body while regarding him with devouring fixity. At least twenty per cent. of the persons who submit to the proof are carried away by visual fascination, chained as by a charm, following me everywhere without trying to detach their eyes from mine."[1]

Bernheim, who is acquainted with the method of Donato, makes some ingenious comments upon it. "The fascination used for the first time by Donato has," he says, "already been described by Doctor Brémaud." Donato, who operates especially on young people, proceeds as follows: "He asks the subject to apply the palms of his hands on his own, which are stretched horizontally, and to press downward with all his strength. The attention and all the physical strength of the subject are absorbed in this manœuvre, while his concentrated innervation toward the muscular effort prevents his thoughts from being distracted. Donato looks at the young man quickly, brusquely, and very near; the operator then turns round the subject, continuing to fix and provoke him with his glance; the latter, as though attracted and fascinated, follows him with wide-open eyes which can no more be detached from his own. It is a matter of suggestion by gesture. The subject understands, by the fixity of the magnetizer's eyes on his, that his eyes must remain attached to the magnetizer's and follow them everywhere. He thinks himself attracted toward him; it is a psychical suggestive fascination, and in no way physical." Upon this nice bit of analysis Donato comments, and comments justly, I think, to the effect that Dr. Bernheim "could have added, to be complete, that the art of hypnotism consists in striking the imagination of the subject in such a manner as to convince him that he attracts him as the magnet attracts the iron, when in reality the iron possesses no magnetic physical virtue; but, on the other hand, certain men are gifted with a prodigious *moral* magnetism, and exercise an irresistible ascendancy over all the persons who surround them."[2]

Another method employed by Donato is this: "I ask the patients," he observes, "to kneel before me and to look steadily into my eyes. Standing before them, I place my hand on their foreheads and incline their heads slightly backward. As soon as they try to straighten them I direct into their pupils an imperative glance which paralyzes them, if they are sensitive to my influence. From the moment that a patient has given proof of submission by following my eyes in my first process, as in remaining nailed to the ground in my second, I can almost always make him go through the successive phases."

The method of inducing the hypnotic state by the aid of passes has already been briefly referred to. Some time ago a writer in the New York *Medical Journal*,[3] Dr. A. L. Wagner, gave an elaborate series of directions, quite fully illustrated by diagrams, for executing these passes in a systematic manner.

These passes are made as follows: "After the subject is seated with his head leaning back against the wall, both feet squarely upon the floor, the palms of the hands upon the knees, the hand of the operator is held about a foot in front of, and about a foot above the level of, the eyes of the subject, with the injunction that the subject look at the hand, and while thus looking is directed to close the eyes. The operator then begins the passes by starting in the middle of the brow, touching the forehead lightly with the tips of the fingers, carrying them outward to right and left, over the brows to the temples, some ten or twelve times. While doing this the subject is directed to keep the eyes rolled back, and to breathe deeply and regularly.

"After making the passes (No. 1), the tips of the fingers are passed down from the middle of the forehead over the cheeks, touching the shoulders, down the arm, touching the hand and, finally, the fingers. The touch must be light, that the subject may not be disturbed (No. 2). These passes are to be repeated some ten or twelve times, in easy succession; then the passes as in No. 1,

[1] The Cosmopolitan for August, 1890, pp. 446 and 447.

[3] The Theory and Practice of Hypnotism. By Albert L. Wagner, M.D. The New York Medical Journal, May 18, 1889, p. 536.

are repeated. Then the tips of the fingers are started higher up on the head, passing down by the ear, over the angle of the jaw on to the neck, compressing somewhat the carotids, and accelerating the flow in the jugulars (No. 3). This is repeated as above, reverting to a few (five or six) passes of No. 1. Then the same passes (No. 3) are continued, but the finger tips pass down the arm and off the fingers, as in No. 2. This is repeated about ten or twelve times (No. 4).

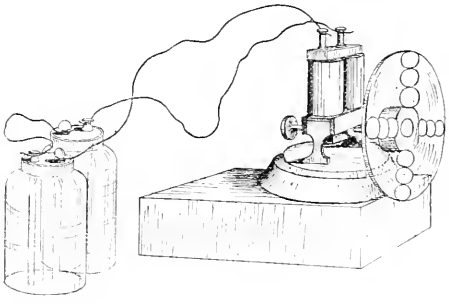

FIG. 1.

"After going over the first, second, and third sets of passes, but a less number of times, the thumbs are started over the brows, down the temples, over the angle of the jaw, on to the blood-vessels of the neck, while the finger tips pass down the back of the head over the occiput, around the neck, down the shoulders and arms, and, finally, touching the fingers (No. 5). This some dozen times, then as in No. 1 and No. 2 then repeat No. 5. After a respite of a minute or two, resort to No 1 and No. 2 several times. Now, if the eyelid is quiet—*i.e.*, not quivering—and the respirations are deep and full, the thumb of the operator is placed over and above the origin of the corrugators, and passed down with a little pressure to a little below the junction of the nasal and frontal bones, while the finger tips start at *b*, pass down over the temple a few inches, to *c*, as in No. 6. This is repeated five or six times, with lightly and gradually increasing pressure, till there is considerable pressure being made, when the operator says: 'Your eyes are tight, you cannot open them, you cannot,' etc., and at the same time passes the fingers of the left hand rapidly down over the brow over the eyes a number of times, close to but not touching the face. This is called fanning, and is useful in confusing the subject, and often keeps the eyes shut where without it they would be opened. In four or five cases out of ten the subject is now under control. It requires one, two, or three, sometimes more, séances to 'get' the remainder of the ten.

"To awaken the subject, make reverse passes over the face and brow. A half dozen passes usually awaken."

Luys adopts a different method, which, as he naively remarks, has the advantage of relieving the operator from all fatigue. It seems that the bird catchers of France employ in their trade a little machine, driven by clockwork, which causes two wooden arms, provided with bright pieces of glass, to revolve in opposite directions. When placed upon the ground and set in motion, the birds become fascinated or hypnotized, and thus easily fall a prey to their captors. This implement of the bird catchers is what Luys employs to hypnotize human beings, several of whom may be influenced at once. The little piece of mechanism is placed on an elevated stand in the centre of a room, and the patients, who sit about in chairs, are told to look at it fixedly. Sometimes no result is obtained the first time, but after a few trials the result is said to be more satisfactory.

I have seen and experimented a little with this instrument of Luys, and have made what seems to me an improvement on it.

The mechanism which I have devised consists, in the first place, of a small electric motor (Fig. 1), which is driven by two small zinc-carbon cells. To the axle of this motor is secured a disk of milk glass six inches in diameter. Upon the outer surface of this disk numerous glass jewels are secured with strong cement. The colors which seem to answer well are light blue, red, pink, and light green. The surfaces of these glass jewels are nicely cut so as to enhance the optical effect. Behind the disk two small lamps are placed to afford the necessary illumination; and when the apparatus is well in motion in a dark or partially darkened room, the effect produced is quite brilliant.

When the patient offers an involuntary resistance, or, from some unknown cause fails to yield readily to this mode of treatment, even when combined with verbal suggestion, I have resorted to a method which represents a combination of fixation, passes, and verbal suggestion. The details of this method are soon told. In the first place, a small electric motor—a diminutive electric lamp may be used instead—is secured upon the head of the operator by means of a cap and chin-strap (Fig. 2.) To the spindle of the motor is attached a large glass diamond. When this is revolved the effect is quite dazzling. The subject being seated in a chair—I prefer an ordinary steamer chair—is told to keep his eyes steadily fixed on the glittering diamond. As the operator faces the subject and sits close to him, he is able to resort to a variety of passes and suggestions which are likely to prove helpful. But this is not all, for the revolving diamond itself renders effective assistance in another way than by fixing the attention of the subject. This is how it operates: Owing to the proximity and elevated position of the diamond, the patient is obliged to both raise and converge his eyes in order to see it; and this dual operation is of itself provocative of fatigue, whereby the occurrence of the hypnotic state is promoted.

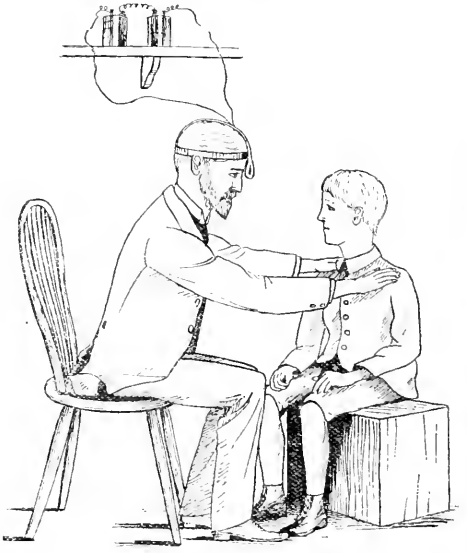

FIG. 2.

Summary.—In closing these brief remarks on a large subject, I cannot refrain from entering a protest against the quixotic exaggerations which are gaining a foothold in this interesting field of investigation—not so much through the efforts of charlatans as of physicians of accredited standing. For example, in looking over the pages of a recent number of *The Fortnightly Review*,[1] I

[1] The Latest Discoveries in Hypnotism. By J. Luys, Physician to La Charité Hospital, etc. The Fortnightly Review, August, 1890, pp. 176, 180, and 182.

find certain statements which are alike opposed to the philosophy of the biologist and the instincts of the practical physician. The clauses to which I take exception are those on the "Influence of chemical and other substances," the "Influence of magnets," and the "Psychic influence of magnets." Most, if not all, of the phenomena described in those paragraphs may be explained by the aid of involuntary or auto-suggestion. True, it is not always easy to trace the manner of the suggestion; but, on the other hand, the enormous influence of suggestion in the induction of hypnotic manifestations has been shown so often that there is no reason to question its causal relation to one class of phenomena more than another. Our position in this regard is rendered the more certain when we remember that the phenomena which a superficial logic ascribes to some occult power exercised by magnets and chemicals—the latter carefully enclosed in glass bottles—may all be invoked by imitations. Thus a wooden magnet or a bottle filled with cotton or carbon, or even quite empty, will answer instead of more "potent" material, so long as the subject, either consciously or unknown to himself, harbors a suspicion that somehow these things are endowed with special attributes. What those attributes are assumed to be, the conduct of the operator is pretty sure to reveal; or if they be not altogether revealed, a hint more or less definite is pretty certain to be given. The suppression of such involuntary suggestion is almost impossible; since even though the operator may be able to control both voice and physiognomy, the acts which he performs are themselves suggestive. As regards "transference," *i.e.*, "the transmission of the nervous state of a diseased subject to a subject hypnotized by means of a magnetic rod,"[1] I must confess that I am sceptical not so much of the appearances themselves as of the alleged causality involved. Whenever and wherever several persons are hypnotized, either at once or successively, the phenomena are always greatly modified by the subjects themselves through involuntary imitations of each other. More than this, the susceptibility of a person to the hypnotic influence may be enhanced if he be present when others are being hypnotized. Hence it is manifest that a hypnotized person may be influenced by those who are in the same condition, or by those who are not. We require no three-branched magnet or other appliance of charlatanism to accomplish these things; aural promptings, or indeed almost any of the other forms of suggestion, are sufficient. The inference to be drawn is, I think, quite plain, and I shall, therefore, drop this phase of the discussion.

Possible Dangers of Hypnotism.—As long ago as 1784, some of the dangers of hypnotism were pointed out by De Puységur, a pupil of Mesmer. The danger to which he referred more particularly was the criminal use which an unprincipled person might make of the ascendancy gained over the subject. These warnings, frequently repeated of late, are not without reason, as the annals of crimes committed during the last sixty years abundantly prove. Rape, kidnapping, and murder are some of the crimes charged to the account of the nefarious hypnotizer.

But these are not the only sources of danger; for experience has abundantly shown that the subject himself may be prompted to commit theft and other species of crime after emerging from the hypnotic condition. This fact, which has already been mentioned, has become the subject of special judicial enactment in several countries.

Finally, the repeated hypnotization of the subject is liable to be followed by more or less dangerous consequences to himself. Inordinate emotionality, impairment of volition, and a tendency to become spontaneously hypnotized, or at least excessively drowsy, are some of the more obvious features of this post-hypnotic condition. I have at the present time under my care a gentleman who exhibits this neurosis—for neurosis it certainly is—in a striking manner. He is a man of rare gifts, he has maintained and still enjoys a high position in the community; and yet his mental decrepitude is so obvious that it is matter of astonishment to me that he has been able to disguise its source so long. Currently he is regarded as a sufferer from mental overwork, and I must confess that I should have had great difficulty in arriving at the true nature of his difficulties, had he not confessed that he had been hypnotized scores of times, and that his present infirmity had come on as the direct result of these abuses—for abuses they certainly were.

Such a person as this is, of course, exposed to manifold dangers, for he had become so susceptible that, not only is it possible for anyone to hypnotize him, but he is able without further assistance to induce in himself the sleep-like state.

Here, then, are the more manifest dangers of hypnotism.

Concerning Possible Therapeutic Uses of Hypnotism.—I am not very sanguine as to the future of hypnotism as a curative agent in nervous or other diseases. According to my own researches—and those researches date back eight years or more—the method is vastly more limited than one would imagine from the exaggerated claims which have been of late advanced in its behalf by over-zealous medical men. Let me mention a few of those limitations. In the first place, only a certain (unknown) percentage of persons are amenable to the hypnotic influences, or, to express it more exactly, only a limited number of persons are hypnotizable with the present means at our command. Secondly, the effects obtainable are evanescent; for, unless we hypnotize the patient so often as to incur the risk of doing him an injury, we cannot hope to perpetuate the suggestions sufficiently to do any good.

From these considerations it follows that the permanent effects which one may hope to produce upon the material economy through this class of psychical forces must be insignificant. Functions may, it is true, be exalted or depressed for the time being, but qualitative changes in the structures themselves are impossible. The internal capsule, the thalamus, the motor convolutions, the sensory tracts in the cord once destroyed, are not to be restored by any form of interference. Moreover, a physiological substitution (in Bernheim's sense) for these and analogous structures, seems well beyond the farthest bounds of physiological probability. Hence, as I have previously mentioned, all attempts to apply hypnotism to the treatment of organic disease are opposed to sound thinking. Indeed, I regard such proposals as hurtful to science, and particularly medical science, inasmuch as the reputation of the profession for sound judgment is thereby greatly jeopardized. The facts which the advocates of such questionable methods have to present are still too few in number, and too meagrely substantiated, to form the basis of affirmative argument. What then is the position which hypnotism may be expected to assume in the neuro-therapy of the future? In my opinion the rôle which it is destined to play is a subordinate one. In the light of its present and past history, I do not see how it can be otherwise. As an adjunct in the management of minor degrees of hypochondria, morbid apprehension, depression, and hysteria, it may sometimes be invoked, but then only as a collateral expedient, and largely with a view to rendering the patient more tractable and amenable to other elements in the plan of treatment. The aid afforded by an appeal to the expectancy of the sick is familiar to every physician; by invoking the aid of the hypnotic state such an appeal may be made with an energy which is not attainable while the patient remains in the ordinary mental condition. But, while the miracles recorded by enthusiastic writers make, like Munchausen's tales, entertaining reading, they are not likely to enter into the sober realities of the consulting-room.

In view of what we now know of it, hypnotism is to

[1] Luys: Op. cit., p. 180.

be dealt with by the physician; for it is evident that a competent medical man is alone in a position to judge of its real or imaginary advantages. Certainly, only such a man should be allowed by our statutes to invoke its assistance in the treatment of diseases, however insignificant.

53 WEST THIRTY-EIGHTH STREET.

FOREIGN BODIES IN THE EYE.[1]

BY DAVID WEBSTER, M.D.,

PROFESSOR OF OPHTHALMOLOGY IN THE NEW YORK POLYCLINIC AND IN DARTMOUTH MEDICAL COLLEGE; SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL, NEW YORK.

IT is by no means an uncommon thing for us to be consulted by patients with foreign bodies lodged in the cornea or under the upper eyelid. In order to ascertain the comparative frequency with which this occurs I looked up the records of the Manhattan Eye and Ear Hospital for a number of years and embracing fifty-four thousand nine hundred and twelve patients with diseases of the eye. Of these no less than twenty-nine hundred had foreign bodies in their cornea, while three hundred and fifty had foreign bodies lodged beneath the upper eyelid. I presume the proportion is much smaller in country districts and in cities where there are no elevated railroads, but every practitioner is liable to meet with these cases, and should know how to handle them.

In the great majority of cases no especial difficulty is encountered. The patient comes to the doctor, tells him he has a speck of dirt or a cinder in his eye, and often locates it for him. The doctor turns over the upper eyelid, sees the foreign particle, and removes it with a little absorbent cotton twisted about the end of a match or tooth-pick, or, if neither be at hand, he brushes it out with the corner of a clean pocket-handkerchief. Or if the speck is not to be seen on the inside of the upper eyelid the doctor turns it back into its natural position and proceeds to inspect the cornea. If the particle is black and large enough to be easily seen, the doctor discovers it at once, puts in a drop or two of a solution of cocaine, no matter of what strength, and after a few minutes proceeds to pick out the offending particle. When very superficial he often succeeds in wiping it off with the absorbent cotton twisted about the end of a slender bit of wood. When a little deeper, he gets it out with an instrument known as a spud. When deeper still, he generally has to resort to the broad cataract-needle, or, better still, a cystotome. But the foreign body may have penetrated so deeply that it is lodged on the membrane of Descemet, or it may have passed through all the coats of the cornea and remain sticking in its posterior surface with a portion of it projecting into the anterior chamber. In such a case none but a skilled hand should attempt its removal. If it escapes and falls into the anterior chamber it will very probably occasion the loss of the eye, and possibly cause the loss of the fellow-eye also, by sympathetic inflammation. It is useless to attempt to extract it with a magnet. It is grasped too firmly by the hard and unyielding tissues of the cornea. The best way is to transfix the cornea near the foreign body with a Beers cataract-knife and press the flat of the blade up against the foreign body, and then, while thus giving it support from behind, pry it out with a cystotome, or broad cataract-needle, as recommended by Dr. C. R. Agnew in the MEDICAL RECORD, vol. i., No. 2. Some recommend transfixing the cornea with a Graefe's cataract-knife, but its blade is too narrow. I tried it once and came very near losing the foreign body. On the other hand, I have used the Beers knife several times with ease and confidence. In a case operated on only a few weeks ago I did not find it necessary to make a counter-puncture. The linear wound made with the Beers knife in these cases heals without any scar visible to the unassisted eye, but there is usually a small, roundish opacity from the healing of the wound where the foreign body was lodged.

If the foreign body is lodged in the conjunctiva of the eyeball it is generally impossible to *pick* it out. The conjunctiva is so loosely attached that it moves with the foreign body before the point of the needle. In such cases I have generally had to resort to delicate forceps and scissors. The foreign body is seized with the forceps, raised up with the conjunctiva in which it is embedded, and snipped out with the scissors. The operator should be very careful to remove as small a portion of the conjunctiva as possible, because a considerable space of sclera is laid bare at the best.

But the patient who comes to us with a foreign body in his cornea very often does not know that it is there. He consults the doctor on account of symptoms of irritation or of inflammation of the eye. Unless the doctor is very careful he will be *misled* in these cases. It is of very little use to give a patient a camphor and borax wash for conjunctivitis while the foreign particle causing it remains in the cornea. I have had two cases under observation recently which impressed on me the importance of careful inspection of the cornea for foreign bodies. The first was a professor of surgery, and author of one of our best works on that subject. He came into my office one morning saying that his left eye was giving him a good deal of trouble; that for the last two or three days it had been subject to cramps and spasms; that sharp pains darted through it at times, and that it watered a good deal off and on. I said, "You have got something in it, haven't you?" He replied that he had no reason to suppose that he had. I looked long and carefully by daylight and by artificial light, and finally found what I sought—a small black speck near the centre of the cornea, so small that it could only be seen when the light was concentrated on it with a lens and when it was viewed at a certain angle. I dropped in some cocaine and removed it, and the doctor had no further trouble with the eye.

The other patient was a lady whose family physician, a man of excellent reputation, had been treating her for more than a week for an acute inflammation of one eye. The eye was red and painful. The cornea was hazy. There was a broad adhesion of the iris to the anterior capsule of the crystalline lens. Upon questioning her I could find no reason why she should have kerato-iritis. There was no syphilitic or rheumatic taint, and she was not aware that she had caught cold or received any injury to the eye. Upon looking at the eye I found a large black speck at the sclero-corneal margin. When I told her I had discovered a foreign body and described its location she declared it was simply a discoloration and had always been there. The doctor had accepted her statement that it was not a foreign body but part of the eye, and had proceeded to treat her for the inflammation. I easily demonstrated that it *was* a foreign body by removing it with the cystotome. I did not see the patient again, but presume that the cause being removed she recovered under the use of atropine and other treatment appropriate for kerato-iritis. It is doubtful, however, whether the synechia posterior will ever be broken up. Let us remember, then, that it is not at all uncommon to find a foreign body in the cornea causing an inflammation where it is not suspected by the patient. In short, where one eye is inflamed without adequate cause a foreign body should always be carefully looked for. I have several times found a loose eyelash projecting from one of the lachrymal puncta and thus keeping up a constant irritation. A single "wild hair" turned in and constantly tickling the eyeball will sometimes do the same thing. On the other hand, physicians are often consulted by patients who are firmly convinced of the presence of foreign bodies under their eyelids, where, on the most careful inspection, none can be found. The explanation that the feeling of irriation is caused by a roughness of the inside of the lid itself often proves unsatisfactory, and such patients sometimes "go the rounds"

[1] Read before the White River Medical Society, July 31, 1890.

of the different eye-doctors, or eye-clinics, to get the imaginary foreign particle removed. The lesson is: Do not depend upon the sensations or the statements of the patient where foreign bodies in the eye are concerned. They are often there when not felt; they are often felt when not there.

If the foreign body has passed through the wall of the eye and lodged anywhere in its interior we have a more serious case to deal with. If it can be seen and extracted the sight may be wholly or partially preserved. If we fail to extract the foreign body the chances are that the eye will be lost, and in a certain proportion of cases the fellow-eye will also be lost, by sympathetic inflammation, leaving the patient totally blind. If the foreign body which has entered the eye is a large one, or if it has already destroyed the sight, the eyeball should be enucleated without delay. If it is very small and is lodged in the crystalline lens, or cannot be found with the ophthalmoscope or by means of oblique illumination, it is best to refrain from operative procedures, to keep the patient quiet, his eyes under atropine and bandaged, and await developments. If the foreign body is lodged in the lens, a cataract is usually developed, and when mature may be extracted with the foreign body in it, and a fair amount of vision restored. The constant changes in the shape of the lens in the act of accommodation may, after a time, force the foreign body out of its substance, and falling through the vitreous chamber to the bottom of the eye it comes in contact with the ciliary body, and sets up a cyclitis. When this occurs the eye should be enucleated. If enucleation is delayed the other eye is almost certain to be lost by sympathetic inflammation. When the location of the foreign body cannot be determined, and there remains a fair amount of useful sight, the patient should be warned that sympathetic inflammation is liable to occur, and that on the first setting in of sensitiveness to light, lachrymation, pain in the eyes, redness, or blurring of sight, he should hasten without delay to the doctor, and have the offending eye taken out if the doctor decides that he has threatened or commencing sympathetic inflammation. In these cases every day's delay increases the chances of blindness many-fold. It is hard to have an eye taken out that still has useful vision, but it is harder still to become blind in both eyes.

When the foreign body is lodged in the anterior chamber it may be removed through a broad incision at the corneal margin; if *steel*, by means of a magnet; if of any substance not susceptible to magnetism, by means of iris forceps, or a small cataract scoop. If the foreign body is lodged in the iris we generally have to remove a piece of the iris along with it. Unfortunately, the processes of sympathetic inflammation may be initiated before the foreign body is removed when lodged in this situation, and yet present no premonitory symptoms. I shall never forget a case of Dr. Agnew's, a child some six or seven years of age, who came to us with a piece of gun-cap plainly visible in the infero-temporal quadrant of iris, and which had been there only a few days. I administered ether and Dr. Agnew performed an iridectomy, removing the piece of gun-cap with the portion of iris in which it was embedded. The eye recovered rapidly, and apparently perfectly, from the injury and from the operation, and the child was taken to Lake George for the summer. In about two months he was brought back to us with irido-cyclitis in the injured eye and sympathetic ophthalmia in the other. In spite of all we could do the little fellow lost the sight of both eyes. The disease had come on insidiously in this case. There was no pain, redness, or photophobia; and the first intimation his parents had that there was anything wrong with his eyes was that they noticed him running against chairs and other objects without any apparent reason. At first they attributed it to carelessness, but on seeing these collisions frequently repeated they began to suspect that his sight was affected, and brought him to Dr. Agnew when too late. The pupils were already filled with lymph, there was total synechia posterior, and there was only perception of light. Further operative interference proved to be of no avail. The case taught me *not to be too sure* that the danger of sympathetic ophthalmia was over when the foreign body was removed.

If the foreign body can be seen suspended in the vitreous humor an attempt should be made to remove it, by the magnet if of steel, by Knapp's roughened foreign body-hook if of brass or of non-attractable substance. If the attempt fails, it is wise to enucleate on the spot.

If the foreign body can be seen lodged in the back wall of the eye, it may sometimes be removed with safety. Dr. George T. Stevens reported a case in which he discovered a piece of metal in that situation. He proceeded to locate it more exactly by puncturing the eye-wall from without with a delicate cataract-needle until he struck the foreign body with the needle. He then cut down upon it and removed it with forceps.

The foreign body sometimes enters the eye with such force that it passes completely through into the orbit.

Less than a month ago I had a case under my care that I strongly suspected to be of that kind. A gasfitter, who was doing repairs only a block away from my office, while cutting off a cast-iron tube, with chisel and hammer, had a piece of the metal fly up and enter his right eye. I saw him within half or three-quarters of an hour from the time of the accident. There was a linear wound of the cornea, not over two millimetres in length, a corresponding opening through the iris near the lower border of the pupil, and with the ophthalmoscope the track of the foreign body could be seen through the crystalline lens, which was already becoming opaque in that region, and at a corresponding point in the back wall of the eye, almost vertically below the optic disk, and one-fourth the distance between it and the ciliary region was a white spot surrounded by hemorrhage. It was impossible to determine whether the foreign body had passed through into the orbit, or had struck the back wall of the eye and rebounded and lodged in its lower periphery. I decided, after consultation with Dr. Noyes, to give the patient the benefit of the doubt and to follow the "expectant" plan of treatment. I kept the patient under observation for ten days or two weeks, kept the eye under atropine and bandaged, and there was very little inflammatory reaction, but a steady increase in the opacity of the lens. His sight in the injured eye, which was $\frac{20}{20}$ when I first saw him, was reduced to $\frac{8}{200}$ before I left the city. When his lens becomes wholly opaque I propose to extract it, provided no sympathetic symptoms occur previously to that necessitating enucleation.

I have more than once seen an eye enucleated for supposed foreign body and none was found either in the eye or in the orbit; although the course of the foreign body could be easily traced through the eye walls into the orbit, yet it had so lost itself in the loose tissues there that it could not be felt with probe or finger. I remember one case, under the care of Dr. Pardee, then one of the surgeons to the Manhattan Eye and Ear Hospital, in which the foreign body—a piece of steel some quarter of an inch in length and irregularly shaped—made its way to the surface, and was removed some three or four months after the eye was enucleated. If the foreign body is in the orbit it need not be sought after very much, as it is not likely to do any harm there.

In conclusion, I beg leave to sum up as follows:

1. Always search carefully for foreign bodies on the cornea and on the conjunctiva in cases of inflammation of one eye coming on suddenly and without other apparent cause.

2. Remove them, when found, with as little injury to the surrounding parts as possible.

3. When a foreign body is lodged within the eyeball, especially in the ciliary region, the patient is in danger of losing the fellow-eye by sympathetic inflammation, whether the foreign body is removed or not. The removal of the foreign body greatly lessens such danger.

4. If the foreign body has already destroyed the sight the eye should be enucleated without delay.

5. If sympathetic inflammation sets in, the sooner the eyeball containing the foreign body is enucleated the better will be the patient's chances of retaining useful sight.

6. If the fellow-eye is attacked with symptoms of severe *sympathetic irritation*, the eye containing the foreign body should be enucleated without waiting for actual sympathetic inflammation.

7. The magnet is serviceable in cases where the foreign body is of attractable material and *can be seen*, and is not firmly embedded in the eye-wall, nor encapsuled with organized lymph.

8. Where the foreign body is small and its lodging-place uncertain the introduction of a magnet into the eye-ball is generally to be deprecated.

9. After the foreign body has been *extracted* from the interior of the eye the patient should be warned that sympathetic inflammation may occur, and, in such a case, should not be neglected.

LAPAROTOMY FOR GUNSHOT WOUND OF INTESTINE.

Four Perforations by Large Bullet; Various Complications; Complete Recovery.[1]

By M. T. SCOTT, A.M., M.D.,

LEXINGTON, KY.

Appreciating the value of clinical records, it has occurred to me that the report of an unusual surgical case might not prove uninteresting. Our most useful information comes from the bedside and operating or post mortem tables rather than from essays on medicine or surgery, valuable though these certainly are. But, lest I trespass too far on your time I will proceed at once to the matter in hand.

On August 6, 1890, I was asked by Dr. W. A. Brock, of Lexington, Ky., to see W. M——, colored, aged twenty-seven. History was as follows: About 7 P.M., on date mentioned, the patient was standing on a street corner diagonally opposite some men who were shooting at each other. A stray bullet struck patient an inch and three-quarters above and to the right of the left anterior-superior spinous process of ilium. The attending physician at once recognized the gravity of the wound, and administering half a grain of morphine by mouth ordered the patient's immediate removal to St. Joseph's Hospital, a mile and a quarter distant.

I first saw the patient, in a dimly lighted small room, about 10.40 P.M. He was a man over six feet high, extremely thin; was lying on his back with legs drawn up, expression anxious, features pinched, extremities cool, this last condition due possibly in some measure to insufficient clothing while in wagon. His pulse was 120, small, and wiry; temperature, 102° F. He complained greatly of radiating pains in abdomen, which was retracted and very hard. Though not probed, the direction of the ball seemed directly backward. An extensive adenitis was found in each groin, each bubo being as large as half a banana, and desquamating in large flakes from previous applications of tincture of iodine. Patient also suffered from gonorrhœal urethritis and cystitis, together with a troublesome bronchitis.

Notwithstanding these very unpromising complications, our cramped quarters, and poor light, I decided to do an immediate laparotomy. This was fully concurred in by Drs. W. A. Brock, E. A. Anderson, and P. H. Molloy, who rendered most valuable assistance. At 11 P.M., four hours after receipt of injury, the inhalation of chloroform was commenced. This anæsthetic was used on account of the necessary proximity of two coal-oil lamps.

The abdomen was scrubbed with bichloride solution, 1 to 2,000. The infected genitals and groins were enveloped in towels wrung out of a solution of twice the above strength. A median incision, four inches long, was made, extending from two inches above to two inches below the navel. As soon as the peritoneum was opened several loops of intestine protruded. These were immediately enveloped in hot, wet towels. In one of these sections of ileum we found four perforations within a distance of four inches. Two of these perforations were within a quarter of an inch of each other, with their long diameters at right angles to long axis of gut. All the perforations were elliptic. The openings were promptly closed by the Czerny-Lembert suture with fine silk. No other visceral or intestinal wounds were found. The intestines were comparatively empty, and but little of their contents had escaped into the cavity. Hemorrhage had been slight. The bullet was not located. The peritoneum was repeatedly washed until the water came away clear. A large glass drainage-tube was used. The abdominal wound was closed by interrupted silk sutures. This step in the operation was very much impeded by the intense rigidity of the abdominal muscles, which did not for a moment yield during the entire operation. This condition baffled our endeavors to secure perfect coaptation of the cut surfaces. A dressing of iodoform, bichloride gauze, and bichloride cotton was held in place by a many-tailed bandage. A similar dressing was used on the wound of entrance. The operation lasted one hour and ten minutes, at the expiration of which time the patient was put in a warm bed, wrapped in blankets, and surrounded by hot bottles. Pulse, 130; temperature, 101° F.

He awakened promptly after the operation, and expressed himself as feeling comfortable. The remainder of the night was passed quietly; no vomiting, no drainage. Nothing was allowed by mouth, but frequent hypodermic injections of whiskey were used. Seven hours after completion of operation, or at 8.30 A.M., August 7th, his pulse was 112, and temperature 100⅖° F.; tube was discharging a sero-sanious fluid without odor. One-quarter of a grain of morphine was used to allay restlessness. Frequent observations of pulse and temperature during the day revealed nothing of interest until 6 P.M. At this time pulse was 116; temperature, 101° F.; the discharge from tube was abundant, brown, and had a distinct feculent odor. Slight delirium was also noted. A hypodermic of one-fourth grain of morphine was given. At 10.30 P.M. pulse was 126; temperature, 101⅘° F.; discharge abundant, and same in character as last noted, though the feculent smell was less marked. August 8th, at 1 A.M., pulse was 132; temperature, 101⅕° F. Vomited a dark fluid, about two ounces. Discharge from tube more serous.

Lest this report grow too lengthy, we will omit further details of pulse, temperature, etc. The temperature never rose above 101¼° F. after the operation, though the pulse reached 132°. Only three-fourths of a grain of morphine was administered after surgical interference, and one half of a grain before it. Nothing was given by the mouth for forty-eight hours, and then ten grains of magnesium sulphate in two drachms of water every hour. At the close of the third day flatus escaped freely; at the same time the tube was withdrawn, as drainage had ceased. Half an ounce of tea was now allowed. Commencing at the ninety-fifth hour purgative doses of Rochelle salts were ordered every two hours. These produced copious movements in eleven hours.

On the sixth day the bullet was located, almost subcutaneous, three inches to the left of spine and one inch below the iliac crest. It was extracted under cocaine anæsthesia. Its removal was accompanied by the discharge of about one drachm of thin, ill-conditioned pus. The bullet was a thirty-eight calibre, conoidal ball, weighing one hundred and forty-three grains, slightly roughened by impingement on ilium, around which it was deflected.

At no time was a catheter used, the cystitis occasion-

[1] Read before the Mississippi Valley Medical Association, at Louisville, Ky., October 9, 1890.

ing frequent and uncontrollable urination, accompanied by considerable vesical tenesmus. Milk was not allowed in any form until the ninth day, and then only as milk punch after purgation. The patient's cough was throughout a troublesome complication.

Intermediate stitches were removed on seventh day, and the remainder on the day following. One small stitch abscess formed, which occasioned no trouble. No gaping or hernia resulted. The patient is at this date, September 8th, walking around the ward. He is much fleshier than before the operation. Cicatrization is complete and firm. His bronchitis, buboes, cystitis, and gonorrhœa have all disappeared.

Remarks.—While it may seem presumptuous to draw conclusions and advocate theories on the experience gleaned from one successful operation, still it seems to me that certain facts are so clearly shown in this case that I may be pardoned for urging certain measures on rather scant clinical experience.

In all cases where there is reasonable ground to think, either from shock, radiating pains, gentle and aseptic probing, or other bedside researches that the peritoneal sac has been invaded, it seems to me that it is our duty to make an exploratory laparotomy and see what damage has been done to the viscera therein contained. While I would not sanction the reckless use of the knife, still the percentage of recoveries from prompt operations, done by competent men, is so immeasurably better than the data furnished by the old, conservative plan, that we cannot longer remain in doubt. As declared by McGuire: "If it is urged that the means suggested are desperate, it can be said in reply that the peril is so extreme that, as now treated, nearly all die; and, I believe, by the means I have pointed out, in gunshot wounds of the peritoneum the patient will exchange an almost certain prospect of death for at least a good chance of recovery."

Ovariotomists have taught us that the peritoneum is not the exquisitely sensitive tissue that we were formerly taught to consider it. On the other hand, it will bear much manipulation if we only clean it, and in certain cases drain it. It has been my lot to see several patients suffering from gunshot wounds of the abdomen. Some have died, all, in fact, except the one now under consideration, and a case operated on by my friend Dr. David Barrow. One patient operated on twenty-four hours after injury died twenty-four hours later. I am satisfied that his last hours were ones of far less suffering than they would have been had he been left without an effort to save his life. On the contrary, I was called, two or three years since, to see a stout, athletic young man who had accidentally shot himself in the abdomen. He declined an operation, and died a death of agony at the end of twenty-four hours, gas and fecal matter escaping from the wound.

In the case under consideration we carried out antiseptic and aseptic methods as well as the circumstances would admit. The large desquamating buboes, so near the field of operation, were a constantly threatening source of infection. The peritoneum and its contents were not allowed that rest and quiet I would so gladly have accorded them. At no time was a catheter used. Shortly after coming from under the chloroform he urinated freely, the act being accompanied by much pain. The vesical tenesmus was distressing during the first week. No trouble resulted about the drainage-tube. Throughout the entire progress of the case his constant cough and uncontrollable attempts to expectorate gave his abdominal organs no peace. Even this did not seem to excite a suspicion of peritonitis.

A large glass drainage-tube was used. Every effort was made to cleanse every nook and corner of the sac, and yet for over four hours at the close of the first day there was a free discharge of chocolate-colored fluid, with a faint feculent odor. Had the peritoneum been closed, and had not the tube proved such an admirable sewer, I am sure that a fatal termination would have rapidly ensued. Where this fluid came from I do not know, probably some fecal extravasation escaped detection. This circumstance, it seems to me, is a strong argument in favor of drainage in these cases. Illustrious operators have left sponges and instruments in the sac. How much easier to overlook a small amount of feculent matter. I care not how painstaking we may be, we cannot see behind all the folds and reduplications of this membrane. It would therefore seem the part of wisdom and caution to use drainage in all peritoneal wounds complicated by visceral, mesenteric, or intestinal injuries.

Operations to be successful must be promptly done. Neither obstacles nor pre-existing diseases need necessarily lead us to decline to operate. This patient recovered in spite of extreme emaciation and other maladies. He was transported over a mile in a wagon over rough roads and was then operated on in a small room with a very poor light.

A CASE OF ACUTE RETRO-BULBAR NEURITIS.[1]

By C. M. HANSEN, A.M., M.D.,

CHICAGO, ILL.

I TAKE the liberty to report from my practice a case of that obscure disease which, from the time of Graefe, has been called acute retro-bulbar neuritis. I do not intend to touch at old theories nor to advance new ones. I simply relate the history of my patient, in the hope that every clinical observation can be of value to the future scientist, who may throw light on the real pathology of this disease.

The patient, Mrs. H——, resident of Pullman, Ill., aged fifty-five, has always been in good health and shows no sign of any chronic disease. She has healthy, grown-up children. On March 20, 1890, she took sick, with a moderate attack of influenza, that was treated with small doses of quinine and antipyrine. Some days later she got a severe headache over the frontal region, that increased in violence during the first week of April, so that she was obliged to stay in bed and use morphine to get sleep. The headache was accompanied by slight fever, but not by delirium nor loss of consciousness. From April 8th her vision became clouded, and thereafter failed rapidly in both eyes, without any subjective light or color symptoms, till she became completely blind on April 11th. The violent headache continued for about one week. After the complete blindness set in, its seat was confined to the frontal region, and its severity necessitated continued use of morphine, then from the middle of April it disappeared gradually. She was now entirely blind, and could not tell light from darkness during four weeks, till May 8th, when she at once began to perceive light. Since that time some vision has slowly returned. She has been fully conscious during the course of the disease. She has had no return of the headache, and all functions are in the best order. I saw her for the first time May 22d. My notes about her case are as follows:

May 22d.—No inflammatory symptoms of the eyes. Condition of both eyes identical. The media are transparent, refraction normal. The pupils dilated *ad maximum*, not reacting to light nor on movements of convergence. Fair perceptibility for light, but poor projection; she is only able to discern light from darkness. Examination of visual field impossible. Pronounced excentric fixation. No nystagmus. The functions of all external muscles of the eyes normal. The sense of smell, taste, and hearing not impaired.

Ophthalmoscopic view of both eyes: Very like an embolism of the central artery in a state of recovery. The margin of the optic disc is clearly defined, of suspiciously white color, the veins abnormally filled, not tortuous, the arteries abnormally small. Retina of pale color, without any evidence of inflammation or bleedings.

[1] Read before the Chicago Medical Society, September 15, 1890.

The patient looks well. No heart disease. The urine normal.

Treatment.—Potassium iodide and strychnine.

June 12th.—Appearance of the eye as last time. Excentric fixation. The visual field of minimal extent, vision improved; she can outline larger objects and discerns bright from darker colors. She moves around in her room without assistance.

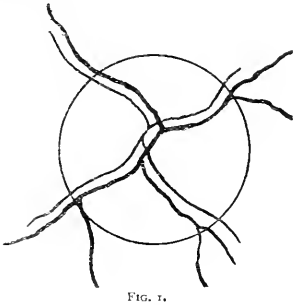

FIG. 1.

Ophthalmoscopic view: The arteries are about normally filled, and are seen with double contours. The disc has a decided atrophied appearance, with exception of the most temporal part.

July 15th.—Appearance as before. Same excentric fixation. She can now see men and horses in the street from her window. She reads with difficulty the large E at five feet distance (V. = $\frac{5}{200}$).

Ophthalmoscopic view: The vessels are normal, the optic disc is atrophied, with exception of a half-moon-shaped section of the temporal part, symmetrical in both eyes. No atrophic spots in the retina.

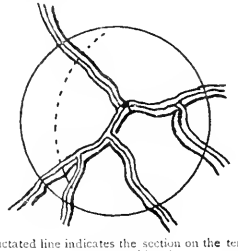

FIG. 2.—The punctated line indicates the section on the temporal border that is not atrophiated.

August 15th.—Unchanged. The vision has not improved during the last six weeks.

Ophthalmoscopic view unchanged. Stationary partial atrophy of the optic nerve.

Otherwise she is in perfect health. Reiterated examinations of her urine have never shown the presence of albumin or casts.

The treatment of the disease has been chiefly hygienic, the potassium iodide as well as the strychnine being apparently of no effect.

Now, in discussing the diagnosis of this case, I may safely exclude the possibility of an hysterical amblyopia as well as of a primary embolism of the central artery. As to an uræmic origin I must repeat that I found no symptoms of Bright's disease in my patient. Furthermore, a uræmic amaurosis would not go so far as atrophy of the optic nerve, unless considerable albuminuric changes had taken place in the retina. As to a toxic amaurosis, there seems here to be no foundation. She did not get quinine nor antipyrine enough even to produce tinnitus aurium of any degree, neither did she present any other sign of idiosyncrasy in regard to these drugs. There is no reason to suppose that syphilis or alcoholism existed.

With exclusion of these causes it will be seen that my case corresponds exactly with the cases described by Graefe as acute retro-bulbar neuritis.

The very rapid and complete loss of vision, simultaneously in both eyes; the later occurring compression of the central vessels of the optic nerve without any inflammatory changes in the bottom of the eye; the more or less complete restoration within a limited time, point to the existence of an infiltration of the optic nerve extending downward from the chiasma. Graefe's cases, as well as those later reported, occurred during or after an attack of acute fever, such as angina, typhoid fever, and especially cerebro-spinal meningitis. I have not been able to find any account of a post-mortem examination, but the theory of a neuritis seems to be strengthened by the similarity of the clinical features to those of an inflammatory optic neuritis in consequence of caries in the bony wall of the foramen opticum.

If I am correct in eliminating in this case all other factors, I believe that the patient had a descendent exudative neuritis, possibly in consequence of a localized plastic meningitis. I believe that the disease was the result of an attack of influenza, the more so as there have been reported several diseases of the nervous system, especially neuritis of the peripheral nerves, directly traceable to the epidemic of influenza of last winter.

Before concluding I would call attention to my patient's excentric fixation. When fixating an object she turns her eye so as to perceive with some point of the retina between the yellow spot and the blind spot. Now, the optic disc of her eye is atrophied, with the exception of a small part on the temporal border, and this is just the part of the optic nerve that furnishes branches for the retina between the optic disc and the yellow spot. This part of the retina is naturally not very perceptible, but it seems that she has been able to educate it from the mere perception of light to a tolerably good perception of the outlines of medium-sized objects.

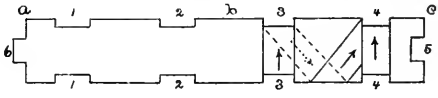
125 STATE STREET.

A SECTIONAL SPLINT

BY F. BIERHOFF, M.D.,

NEW YORK.

SOMETIME ago, during a discussion on the ambulance corps in the National Guard, my friend Major Bruce, Surgeon to the Eighth Regiment, N. G. S. N. Y., suggested to me that I devise a sectional splint that should be strong, firm, and compact, so as to admit of easy transportation and use on the field. He went further, and gave me such ideas as led to my making a splint which, I thought, would fulfil these requirements. On practical trial, however, I found it not sufficiently rigid and strong, and requiring so great a time to put together that I decided, if possible, to alter it so as to obviate these defects. Several successive designs were tried, but all found to be more or less defective, until finally I hit upon the present. This consists of five pieces of white-wood, or any other light, strong wood, each eighteen inches long, by three wide, by three-eighths inch thick. (See Figure.)



The depressed portions are one and one-half inch in length and three-sixteenths in depth, three inches apart, and one and one-half inch from either end, so that, with the sections in position, all are three inches apart. The tongue and groove are one inch wide by one-half inch deep. (The tongue adds one-half inch to the length of the splint.)

Five sections (or three with two link sections) make a long thigh splint reaching to the axilla. Three (or two

though occasionally it will fail. It also is hardly equal to the task of quieting epileptics in the furious excitement to which they are subject.

Its continuous administration has no tendency to produce a habit, a danger which lurks in every dose of morphia, chloral, and such drugs.

As a condensed statement of the indications and contra-indications for the use of paraldehyde, I have arranged the following synopsis of my experience with the drug:

Paraldehyde may be given in doses varying from thirty minims to three drachms, bearing in mind that continued use establishes a tolerance, which must be met by a gradual increase in dose.

It is in reasonable doses the safest of all hypnotics, and is especially so in old and feeble persons with heart lesions.

It is not constipating, but laxative, and has no tendency to impair appetite or nutrition.

It can be given in nearly all cases of insomnia, and will fail only in a small percentage of cases. It does not relieve pain, nor will it produce sleep in cases of great excitement, such as occur in mania.

It stimulates rather than depresses, and a low state of vitality is no contra-indication to its use.

It is contra-indicated in cases of gastric or intestinal disorders, and probably in diseases of the kidney.

Progress of Medical Science.

Successful Removal of a Hydatid Cyst Pressing on the Motor Region.—Dr. Graham and Mr. Clubbe report an interesting case of severe brain lesion successfully treated by operation. The case was that of a youth, aged sixteen years, whose previous history showed no serious illness. At ten years of age, however, he was unconscious for two days, apparently from cerebral laceration after a fall. At the beginning of the present year his memory gradually failed, and in addition to suffering from giddiness and sickness, he gradually became blind in the left eye. Weakness in both legs next appeared, and right brachioplegia. On admission to the Prince Alfred Hospital, under Dr. Graham, both disks showed post-neuritic atrophy. He was treated with large doses of bromide and iodide of potash, and improved very much in motor power. However, he had a fit, after which the right hemiplegia was much worse, and stupor began. Exposure of the arm area in the left hemisphere by trephining was then performed by Mr. Clubbe, and a hydatid cyst removed, having been found to be simply pressing on the "motor" area. The wound was closed and healed by the first intention. There was some subsequent oozing of cerebro-spinal fluid, owing, perhaps, to the employment of a drainage-tube, but the patient made an excellent recovery, and has now regained the lost power. Unfortunately, the operation was performed too late to prevent atrophy, and so the patient, it is to be feared, is permanently blind. In every respect, however, the case is a most valuable contribution to the literature both of cerebral surgery and of hydatid disease.—*Australasian Medical Gazette.*

Tubercular Peritonitis, Infection of an Ovarian Cyst.—Dr. Sanger recently described, before the Obstetrical Society of Leipzig, a case to be noted alike by surgeons who perform abdominal section, and by all who are interested in the pathology of tubercle. A woman, aged sixty-seven, was subject to an ovarian cyst, which had repeatedly been tapped. Dr. Sanger operated, and removed a multilocular glandular cyst, weighing sixteen pounds. The contents were colloid. There were universal adhesions readily broken down without much hemorrhage. Then the operator found that tubercular peritonitis existed, proceeding from the Fallopian tube, which was removed with the cyst. The affected tube was as thick as a man's finger; its cavity contained cheesy matter; its serous coat was covered with miliary deposit. The wall of the cyst was beset with yellow patches, which on microscopic examination, proved to be true tubercular deposit. The uterine discharge, muco-purulent and full of cheesy flakes, indicated tubercular disease of the uterus, but no tubercle bacilli were detected. The patient recovered, it is reported, without any rise of temperature. This fact, in connection with the great age of the patient and the tubercular disease, is certainly remarkable. The tapping had no doubt caused the tubercular infection of the cyst wall.—*British Medical Journal.*

The Bacillus of Purulent Urine.—Some experiments have been made in the laboratory of Professor Strauss, in Paris, by Dr. Krogius, on the puriform urine of ten patients suffering from chronic stricture, with catarrh of the bladder and pyelo-nephritis. In one of these cases a bacillus was found of rather polymorphous appearance, resembling a small mobile pencil with rounded ends. The bacillus was from 1.8 μ to 3.6 μ in length, with a breadth equal to one-third of its length. When cultivated the length became considerable, but it developed no spores. It was easily dyed by aniline, but with equal facility decolorized by Gram's method, and it liquefied gelatine. At a high temperature it developed most peculiar colonies. They were distinguished by a strong characteristic odor resembling that of purulent urine. The development of ammonia was very marked. The bacillus very quickly decomposes urea into carbonate of ammonia and water. When newly cultivated and injected in doses of half a cubic centimetre into the subcutaneous connective tissue, veins, or peritoneum of rabbits, it often caused death in two hours, and never took more than two days to act fatally. Older bacilli are still more poisonous. The puncture shows first œdema and redness, and then the epidermis becomes gangrenous, with an ammoniacal odor. The animals themselves are, in a few hours after the injection, in a state of high fever, prostrated, and suffering from profuse diarrhœa, and ultimately coma comes on, during which they sometimes die in convulsions. The bacillus is called by the author "liquefaciens septicus."—*The Lancet.*

Reunion of Cut-off Tongue.—Dr. N. C. Davis, of Good Thunder, Minn., in September, 1884, was summoned to see a boy seven years of age who had been kicked by a horse on the right cheek, breaking off the first bicuspid tooth. The tongue was cut entirely off at the junction of the tip with the base, or the posterior portion of the frænum linguæ, with the exception of a few fibres of the tongue and mucous membrane on the right side. When Dr. Davis arrived, the end of the tongue was protruding from the mouth. The hemorrhage was controlled by a dilute solution of persulphate of iron. Dr. Davis drew the base of the tongue forward with a tenaculum. Then the apex was brought into apposition with the base, and secured by five silk ligatures above on the dorsum, and seven below. The boy stood the operation well, and the hemorrhage was trivial. The balance of the treatment consisted in syringing out the mouth twice daily with a solution of boracic acid and putting patient upon a liquid diet. The tongue healed nicely, with the exception of a small portion on the left side, which sloughed out and left a small notch, which was nearly replaced by granulation. The doctor discharged the patient in about three weeks, with the tongue full length and articulation good.—*Northwestern Medical Journal.*

The Treatment of Acute Diseases.—According to Dr. N. S. Davis, if we would reach the highest degree of success in the treatment of acute general diseases, we must keep distinctly in mind the following propositions: 1. We

The patient looks well. No heart disease. The urine normal.

Treatment.—Potassium iodide and strychnine.

June 12th.—Appearance of the eye as last time. Excentric fixation. The visual field of minimal extent, vision improved; she can outline larger objects and discerns bright from darker colors. She moves around in her room without assistance.

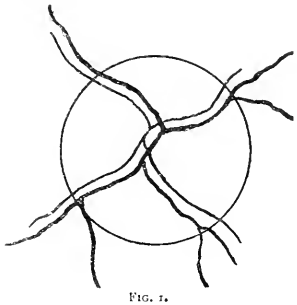


FIG. 1.

Ophthalmoscopic view: The arteries are about normally filled, and are seen with double contours. The disc has a decided atrophied appearance, with exception of the most temporal part.

July 15th.—Appearance as before. Same excentric fixation. She can now see men and horses in the street from her window. She reads with difficulty the large E at five feet distance ($V. = \frac{5}{200}$).

Ophthalmoscopic view: The vessels are normal, the optic disc is atrophied, with exception of a half-moon-shaped section of the temporal part, symmetrical in both eyes. No atrophic spots in the retina.

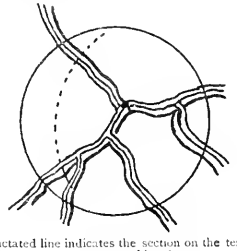

FIG. 2.—The punctated line indicates the section on the temporal border that is not atrophiated.

August 15th.—Unchanged. The vision has not improved during the last six weeks.

Ophthalmoscopic view unchanged. Stationary partial atrophy of the optic nerve.

Otherwise she is in perfect health. Reiterated examinations of her urine have never shown the presence of albumin or casts.

The treatment of the disease has been chiefly hygienic, the potassium iodide as well as the strychnine being apparently of no effect.

Now, in discussing the diagnosis of this case, I may safely exclude the possibility of an hysterical amblyopia as well as of a primary embolism of the central artery. As to an uræmic origin I must repeat that I found no symptoms of Bright's disease in my patient. Furthermore, a uræmic amaurosis would not go so far as atrophy of the optic nerve, unless considerable albuminuric changes had taken place in the retina. As to a toxic amaurosis, there seems here to be no foundation. She did not get quinine nor antipyrine enough even to produce tinnitus aurium of any degree, neither did she present any other sign of idiosyncrasy in regard to these drugs. There is no reason to suppose that syphilis or alcoholism existed.

With exclusion of these causes it will be seen that my case corresponds exactly with the cases described by Graefe as acute retro-bulbar neuritis.

The very rapid and complete loss of vision, simultaneously in both eyes; the later occurring compression of the central vessels of the optic nerve without any inflammatory changes in the bottom of the eye; the more or less complete restoration within a limited time, point to the existence of an infiltration of the optic nerve extending downward from the chiasma. Graefe's cases, as well as those later reported, occurred during or after an attack of acute fever, such as angina, typhoid fever, and especially cerebro-spinal meningitis. I have not been able to find any account of a post-mortem examination, but the theory of a neuritis seems to be strengthened by the similarity of the clinical features to those of an inflammatory optic neuritis in consequence of caries in the bony wall of the foramen opticum.

If I am correct in eliminating in this case all other factors, I believe that the patient had a descendent exudative neuritis, possibly in consequence of a localized plastic meningitis. I believe that the disease was the result of an attack of influenza, the more so as there have been reported several diseases of the nervous system, especially neuritis of the peripheral nerves, directly traceable to the epidemic of influenza of last winter.

Before concluding I would call attention to my patient's excentric fixation. When fixating an object she turns her eye so as to perceive with some point of the retina between the yellow spot and the blind spot. Now, the optic disc of her eye is atrophied, with the exception of a small part on the temporal border, and this is just the part of the optic nerve that furnishes branches for the retina between the optic disc and the yellow spot. This part of the retina is naturally not very perceptible, but it seems that she has been able to educate it from the mere perception of light to a tolerably good perception of the outlines of medium-sized objects.

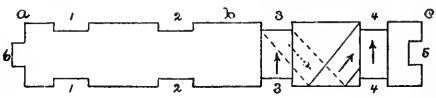
125 STATE STREET.

A SECTIONAL SPLINT

BY F. BIERHOFF, M.D.,

NEW YORK.

SOMETIME ago, during a discussion on the ambulance corps in the National Guard, my friend Major Bruce, Surgeon to the Eighth Regiment, N. G. S. N. Y., suggested to me that I devise a sectional splint that should be strong, firm, and compact, so as to admit of easy transportation and use on the field. He went further, and gave me such ideas as led to my making a splint which, I thought, would fulfil these requirements. On practical trial, however, I found it not sufficiently rigid and strong, and requiring so great a time to put together that I decided, if possible, to alter it so as to obviate these defects. Several successive designs were tried, but all found to be more or less defective, until finally I hit upon the present. This consists of five pieces of white-wood, or any other light, strong wood, each eighteen inches long, by three wide, by three-eighths inch thick. (See Figure.)



The depressed portions are one and one-half inch in length and three-sixteenths in depth, three inches apart, and one and one-half inch from either end, so that, with the sections in position, all are three inches apart. The tongue and groove are one inch wide by one-half inch deep. (The tongue adds one-half inch to the length of the splint.)

Five sections (or three with two link sections) make a long thigh splint reaching to the axilla. Three (or two

though occasionally it will fail. It also is hardly equal to the task of quieting epileptics in the furious excitement to which they are subject.

Its continuous administration has no tendency to produce a habit, a danger which lurks in every dose of morphia, chloral, and such drugs.

As a condensed statement of the indications and contra-indications for the use of paraldehyde, I have arranged the following synopsis of my experience with the drug:

Paraldehyde may be given in doses varying from thirty minims to three drachms, bearing in mind that continued use establishes a tolerance, which must be met by a gradual increase in dose.

It is in reasonable doses the safest of all hypnotics, and is especially so in old and feeble persons with heart lesions.

It is not constipating, but laxative, and has no tendency to impair appetite or nutrition.

It can be given in nearly all cases of insomnia, and will fail only in a small percentage of cases. It does not relieve pain, nor will it produce sleep in cases of great excitement, such as occur in mania.

It stimulates rather than depresses, and a low state of vitality is no contra-indication to its use.

It is contra-indicated in cases of gastric or intestinal disorders, and probably in diseases of the kidney.

Progress of Medical Science.

Successful Removal of a Hydatid Cyst Pressing on the Motor Region.—Dr. Graham and Mr. Clubbe report an interesting case of severe brain lesion successfully treated by operation. The case was that of a youth, aged sixteen years, whose previous history showed no serious illness. At ten years of age, however, he was unconscious for two days, apparently from cerebral laceration after a fall. At the beginning of the present year his memory gradually failed, and in addition to suffering from giddiness and sickness, he gradually became blind in the left eye. Weakness in both legs next appeared, and right brachioplegia. On admission to the Prince Alfred Hospital, under Dr. Graham, both disks showed post-neuritic atrophy. He was treated with large doses of bromide and iodide of potash, and improved very much in motor power. However, he had a fit, after which the right hemiplegia was much worse, and stupor began. Exposure of the arm area in the left hemisphere by trephining was then performed by Mr. Clubbe, and a hydatid cyst removed, having been found to be simply pressing on the "motor" area. The wound was closed and healed by the first intention. There was some subsequent oozing of cerebro-spinal fluid, owing, perhaps, to the employment of a drainage-tube, but the patient made an excellent recovery, and has now regained the lost power. Unfortunately, the operation was performed too late to prevent atrophy, and so the patient, it is to be feared, is permanently blind. In every respect, however, the case is a most valuable contribution to the literature both of cerebral surgery and of hydatid disease.—*Australasian Medical Gazette.*

Tubercular Peritonitis, Infection of an Ovarian Cyst.—Dr. Sanger recently described, before the Obstetrical Society of Leipzig, a case to be noted alike by surgeons who perform abdominal section, and by all who are interested in the pathology of tubercle. A woman, aged sixty-seven, was subject to an ovarian cyst, which had repeatedly been tapped. Dr. Sanger operated, and removed a multilocular glandular cyst, weighing sixteen pounds. The contents were colloid. There were universal adhesions readily broken down without much hemorrhage. Then the operator found that tubercular peritonitis existed, proceeding from the Fallopian tube, which was removed with the cyst. The affected tube was as thick as a man's finger; its cavity contained cheesy matter; its serous coat was covered with miliary deposit. The wall of the cyst was beset with yellow patches, which on microscopic examination, proved to be true tubercular deposit. The uterine discharge, muco-purulent and full of cheesy flakes, indicated tubercular disease of the uterus, but no tubercle bacilli were detected. The patient recovered, it is reported, without any rise of temperature. This fact, in connection with the great age of the patient and the tubercular disease, is certainly remarkable. The tapping had no doubt caused the tubercular infection of the cyst wall.—*British Medical Journal.*

The Bacillus of Purulent Urine.—Some experiments have been made in the laboratory of Professor Strauss, in Paris, by Dr. Krogius, on the puriform urine of ten patients suffering from chronic stricture, with catarrh of the bladder and pyelo-nephritis. In one of these cases a bacillus was found of rather polymorphous appearance, resembling a small mobile pencil with rounded ends. The bacillus was from 1.8 μ to 3.6 μ in length, with a breadth equal to one-third of its length. When cultivated the length became considerable, but it developed no spores. It was easily dyed by aniline, but with equal facility decolorized by Gram's method, and it liquefied gelatine. At a high temperature it developed most peculiar colonies. They were distinguished by a strong characteristic odor resembling that of purulent urine. The development of ammonia was very marked. The bacillus very quickly decomposes urea into carbonate of ammonia and water. When newly cultivated and injected in doses of half a cubic centimetre into the subcutaneous connective tissue, veins, or peritoneum of rabbits, it often caused death in two hours, and never took more than two days to act fatally. Older bacilli are still more poisonous. The puncture shows first œdema and redness, and then the epidermis becomes gangrenous, with an ammoniacal odor. The animals themselves are, in a few hours after the injection, in a state of high fever, prostrated, and suffering from profuse diarrhœa, and ultimately coma comes on, during which they sometimes die in convulsions. The bacillus is called by the author "liquefaciens septicus."—*The Lancet.*

Reunion of Cut-off Tongue.—Dr. N. C. Davis, of Good Thunder, Minn., in September, 1884, was summoned to see a boy seven years of age who had been kicked by a horse on the right cheek, breaking off the first bicuspid tooth. The tongue was cut entirely off at the junction of the tip with the base, or the posterior portion of the frænum linguæ, with the exception of a few fibres of the tongue and mucous membrane on the right side. When Dr. Davis arrived, the end of the tongue was protruding from the mouth. The hemorrhage was controlled by a dilute solution of persulphate of iron. Dr. Davis drew the base of the tongue forward with a tenaculum. Then the apex was brought into apposition with the base, and secured by five silk ligatures above on the dorsum, and seven below. The boy stood the operation well, and the hemorrhage was trivial. The balance of the treatment consisted in syringing out the mouth twice daily with a solution of boracic acid and putting patient upon a liquid diet. The tongue healed nicely, with the exception of a small portion on the left side, which sloughed out and left a small notch, which was nearly replaced by granulation. The doctor discharged the patient in about three weeks, with the tongue full length and articulation good.—*Northwestern Medical Journal.*

The Treatment of Acute Diseases.—According to Dr. N. S. Davis, if we would reach the highest degree of success in the treatment of acute general diseases, we must keep distinctly in mind the following propositions: 1. We

must as early as practicable separate the patient from the further action of both the specific and predisposing causes of his disease, by surrounding him with pure air and as perfect sanitary conditions as possible; and as the living animal system uniformly tends to either destroy or eliminate the specific morbific causes by its own metabolic changes, we should carefully avoid the use of such remedies as either directly or indirectly retard or prevent such normal metabolic processes, even for the repression of one or more prominent symptoms. On the contrary, we must use such general alterative and antiseptic remedies as are known to sustain and correct such processes, and thereby aid in hastening the destruction or elimination of the disturbing *materies morbi*, whether they consist of living germs, chemical ptomaines or leucomaines, or only excretory matters abnormally retained in the system. 2. As the pyrexia or high temperature results mostly from interference with the processes of heat-dissipation, especially in the ordinary continued fevers, we must further aid in restoring these processes by gently promoting natural elimination and the direct abstraction of heat by sponge-baths, and in excessive cases by wrapping in the cold wet sheet, all of which exert a restorative influence on the vaso-motor, cardiac, and respiratory nerve-centres; while, with equal care, we avoid administering such doses of internal antipyretics and alcoholics as diminish heat-production by retarding both blood and tissue metabolism, and equally depress nerve sensibility and force. 3. Again, as every specific cause capable of producing the complex assemblage of morbid phenomena that constitute a general fever, has displayed a tendency to induce special local morbid conditions in some one or more of the important tissues or organs during the progress of the general disease, as in the glands of the ileum, mesentery, and spleen in typhoid, the stomach, duodenum, and liver in periodical and yellow fevers, etc., we must early and accurately use such remedies as palliate or modify these local developments wherever they may be manifested, and thereby prevent such structural changes in these directions as might otherwise end in fatal exhaustion. 4. Finally, as all acute morbid processes, when established, are progressive through the successive stages of increase, culmination, and decline, or destruction of the patient, we must carefully adjust both our remedial agents and nutrient materials to the actual stage of progress of the disease, and the capacity of the patient to receive and appropriate the same; ever remembering that the same remedial agent that might be of great value in the first stage, might be injurious or even destructive if used at the stage of culmination, or still more in that of decline. Hence specific remedies for acute general diseases can be rationally or successfully used only when aimed at the destruction or elimination of the specific causes, and in the first stage of morbid process. Indeed, the chief benefits thus far derived from the use of antiseptics and germicides, have been as preventives in the incubative and prodromic stages, rather than as curatives after active morbid processes have become manifest.—*Journal of the American Medical Association.*

The Question of Hemorrhage after Operations.—One of the chief factors contained in the prognosis of any surgical operation is the question of hemorrhage, and the extent of the latter will depend upon the nature of the operation, and the age, sex, and constitutional state of the patient. As is well known, loss of blood is accompanied by a corresponding decrease of the number of red blood-corpuscles and a reduction of the quantity of hæmoglobin. If, therefore, by means of the hæmometer we estimate the quantity of hæmoglobin before and after an operation, we can form an approximate idea of the extent of the hemorrhage. This had been recently attempted by Professor Mikulicz, the result of whose investigations are formulated in a paper read before the late Congress of the German Surgical Society. Dr. Mikulicz has examined the blood of four hundred persons, at various periods before and after operations, making altogether four thousand examinations. These revealed that the largest quantity of hæmoglobin is present in the blood between the ages of twenty and thirty years, while in children under ten years it is at a minimum. In females the quantity is less than in males at all periods of life. An interesting part of these investigations is that relating to the time required for the regeneration of the hæmoglobin after hemorrhages, the rapidity of its formation depending, of course, upon the severity of the hemorrhage. The most rapid reproduction was observed in young men, the average time required being ten days, while in aged females it was prolonged to three times this period. The old observation was confirmed, that children and aged persons are more seriously affected by losses of blood than individuals of middle age. In general, for every five per cent. of hæmoglobin lost, five days of regeneration were required. As regards the maximum loss of this element which patients were able to survive, it was noted that a reduction of twenty per cent. was always followed by a fatal result. As might be imagined, the quantity of hæmoglobin was always found considerably reduced in persons suffering from tuberculosis, and the period of regeneration after operations was always six or eight days longer than under normal conditions. The same was observed in cases of syphilis, actinomycosis, and malignant tumors, while benign growths which did not react on the general health were without influence. It is also a curious fact that the prolonged administration of chloroform in operations unattended with loss of blood, produced a decrease of the hæmoglobin. The author thinks that the knowledge gained by a large number of observations of this nature may prove of inestimable value to the surgeon. For, if it is possible to determine the minimal quantity of hæmoglobin necessary to sustain life in persons of different age, and suffering from various diseases, and to estimate the amount of loss in different surgical procedures, we will be able to decide with mathematical certainty whether the patient is at any given time in a condition to survive an operation.—*International Journal of Surgery.*

The Microbe of Granular Ophthalmia.—Dr. Shongolowicz has described a plan of preparing and staining specimens of granular ophthalmia by means of which the true nature of the microbe which is the cause of this disease can be made out (*The Lancet*). This is not, as has been supposed by other observers, a micrococcus, but a short bacillus, from 0.75 μ to 2 μ in length and 0.3 μ to 0.5 μ in breadth. It is not easy to stain, gentian violet being on the whole the best stain for the purpose; different segments, too, take very different degrees of stain, and this it is which has given rise to the idea that the microbe is a micrococcus arranged in lines or chains. A number of experiments were made on the eyes of animals, with the result that in two cases an affection was produced which bore considerable resemblance to granular ophthalmia.

Contagious Tuberculosis.—Dr. Ollivier has recently reported a case of contagious tuberculosis at Neuilly. A family of seven occupied a house in the Rue du Pont. In the course of two years five out of the seven were attacked with tuberculosis; two are dead and three are seriously ill. Inquiry showed that the house had formerly been occupied by a family suffering from tuberculosis; in 1887 a child died in it from that disease. It is supposed that this case, which was the first, is the origin of the contamination. Dr. Ollivier concludes from this, and the other cases brought under his notice, that it is dangerous to inhabit a house which has been previously inhabited by tuberculous patients, unless it be thoroughly disinfected. The paper should be stripped off, and the walls whitened with lime; the wainscotting and floor should be scraped and washed with a 1 in 1,000 solution of corrosive sublimate.

MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHERS

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, November 8, 1890.

IS DIABETES MELLITUS EVER CONTAGIOUS?

MANY theories have been advanced to explain the origin of this complaint. It has been ascribed to heredity, to excessive use of certain foods, to sudden grief, etc. It is probable that diabetes mellitus is not a single disease, but rather a symptom which is common to several disease processes.

In the *Berlin. Klin. Woch.*, No. 20, 1890, the theory is advanced by Dr. Schmitz that certain cases of diabetes mellitus arise by contagion. He opposes the theory of an emotional cause, on the ground that in cases under his care the reception by diabetic patients of the most depressing news, which has almost driven them into insanity, has had no influence whatever upon the amount of sugar excreted. His experience with diabetes mellitus embraces now more than two thousand cases. He was first led to suspect that the disease could be communicated from one patient to another by observing the frequency with which husband and wife were affected. He has now collected twenty-six cases, in which persons in good health (generally wives), free from hereditary taint, not great sugar eaters, and who have never had rheumatism, have suddenly manifested unmistakable symptoms of the disease, after prolonged and confining attendance upon diabetic patients not related to them by blood.

Although his theory conflicts with the teachings of eminent writers, he feels that such a rich experience warrants an open expression of his belief. Circumstances have hindered him from supporting his views by experiments looking toward the production of the disease in animals. He gives, however, instead of such records, a brief account of several of the more striking cases in his practice.

In one case, a man of forty-eight years, suffering with diabetes for two years, was treated at the sanatorium. Two years later he returned still diseased, and his wife, a previously robust and healthy woman, came with him to be treated for the same trouble, which led to her death a few months later. No other cause than contagion could be discovered.

In another instance, a man of thirty-eight years, known to have had diabetes for one year, died in the sanatorium a month after arrival. Two months after his death his widow, who, when she brought him to the sanatorium, had been a picture of health and who had nursed him there, asked advice for an intense pruritus, which was readily traced, after careful examination, to diabetes mellitus. She presented no evidence of hereditary predisposition to the disease, and no other cause than contagion could be found. She returned next summer for treatment, and in the autumn married again, the husband being healthy, of good family history, and not her blood-relation.

Two years later they returned together, both having plain symptoms of diabetes mellitus.

In a third case, a lady who died of diabetes had been attended most faithfully by a young friend twenty-five years of age. This young lady was in full health and very robust, without family history of diabetes or any other known predisposing influence. Shortly before her friend's death she began to feel somewhat out of health, but this she ascribed to the strain of nursing. Several months after her friend's death, on her return from a trip to Switzerland, she sought advice on account of debility and loss of flesh, which had persisted in spite of mountain air and the milk-cure. Her urine contained five per cent. of sugar.

Dr. Debove, of Paris, has also observed cases very similar to those reported by Schmitz, and made his observations the subject of a paper read before the Hospitals Medical Society, in July, 1889. He does not seek the explanation of these occurrences in contagion, however, but rather believes with Lecorché that the coincidence of the same disease in man and wife, or in persons living together, is due to the fact that both make use of the same unsuitable and defective nourishment, and that they share with each other various mental anxieties and other etiological conditions.

RESUSCITATION OF THE APPARENTLY DROWNED.

FOR the revival of persons who have been nearly drowned, two chief methods (with numerous slight modifications of each) are in use: the "Sylvester" and the "Marshall Hall." In 1862, a committee appointed by the Royal Medical and Chirurgical Society of London, to consider the rival claims of the two methods, reported in favor of the method of Sylvester, on the ground that the amount of air introduced into healthy lungs by this method was double that introduced by the method of Marshall Hall. The committee recommended that the body should be placed at an angle of thirty degrees, face downward, with the head lower than the feet, the mouth being open and the tongue drawn forward. The escape of fluids might be assisted by slight pressure on the back. After a few seconds the body should be laid back downward with a cushion under the shoulders, the tongue hanging out of the mouth. About fourteen times a minute the arms should be drawn above the head and then lowered and pressed, by the elbows, against the chest.

In the Transactions of the above-mentioned society for 1889, Dr. Bowles criticises very earnestly the conclusions of the committee, which had been indorsed by the society. The committee based its report upon experiments made with the *empty* lungs of animals. The physician, however, has to deal with human beings whose lungs are filled with fluid, mixed with air in a blood-stained froth. Under these conditions the most useful method must provide not only for the inspiration of air, but also for the escape of this frothy liquid from the deeper air-passages.

The sudden introduction of a large quantity of air by the Sylvester method is injurious, because at the same time the froth is drawn deeply into the finest tubes, which before contained a little air. By the Marshall Hall method, however, the air is introduced gently and in small quantities, and the froth is not drawn in more deeply, but is gradually expelled with each expiratory movement. Dr. Bowles supports his statements by the recital of a number of cases which he has treated.

After the patient has been placed for a moment with face downward to allow the escape of water from the mouth and throat, he is turned on the side and *kept on that side* continuously, except when (about fifteen times a minute) the body is rolled for a few seconds upon the face again. By *keeping the same side always up* the lung on that side becomes clear. Turning first one and then the other side up is dangerous, because thereby the partly cleared lung is suddenly flooded with fluid from the lung which was downward. It is better to clear one lung entirely than to have both half cleared. Each time the body is turned upon the face a little more froth and water escapes from the mouth and nostrils. If one lung is thus cleared it may escape the inflammation which results from the inspiration of water. When the upper lung has been almost cleared, Dr. Bowles finds it useful to raise the upper arm above the head as in the Sylvester method, since the entrance of larger quantities of air into the lung is now safe. Pressure on the back at each pronation assists the escape of water somewhat, and it has a good influence on the heart, aiding the propulsion of blood toward the lungs. The continued use of the prono lateral method is an excellent mode of keeping the pharynx clear of obstruction.

POST-MORTEM PRAISE.

The great majority of our readers are probably unfamiliar with the name of the late Dr. Handfield Jones. Yet his memory has just received a tribute which no one can read without feeling warmly toward its author, Dr. Wilks, or without feeling a special interest in the object of the eulogy. We publish it elsewhere, for it is helpful reading. One can but think, however, of the pleasure it would have given Dr. Jones if he could have had such a testimonial when alive. Post mortem tributes have usually an empty sound, even when they are sincere and eloquent like that of Dr. Wilks. The regret comes, as we have suggested, that it could not have been made to warm the heart and cheer the declining years of him who has passed away.

The German practice of having "jubilees," in which the life-work of the aged savant is reviewed and praised, has many things to commend, and might well be adopted in other countries.

RUSTY-NAIL WOUNDS AND THE BACILLUS OF MALIGNANT ŒDEMA.

Before the era of bacteriology various unsatisfactory explanations were given by surgical writers of the well-known danger which attends the reception of punctured wounds from dirty or rusty implements and from nails or splinters which have become covered with dust or soil. Even when the doctrine of antisepsis had opened the eyes of practitioners to the source of infection of wounds in hospitals from the conveyance of disease-matter from patient to patient, the cause of danger from old nails and dusty or earth-covered splinters, in country homes, remained a mystery, for it could not be supposed that they were the carriers of disease-matters, and it was well known that deep incised wounds were not in themselves, even when made with blunt instruments, more dangerous to life than other wounds. Why, then, the frequency of tetanus and gangrene after wounds from dusty or earth-covered objects? That it is due to rust, when from nails, is impossible, for rust is the oxide of iron, which is harmless.

By the patient researches of laboratory workers this problem has now been solved in a way which is both interesting and utterly unexpected. It seems that there is a class of microscopic organisms which is characterized by the inability of the organisms to grow and multiply in the presence of oxygen (or of air). To this class belong certain organisms which have been obtained from the tissues of animals dying of certain forms of gangrene which follow such wounds as have just been mentioned. Their life-history most beautifully explains the danger of these wounds.

The clinical results of such a wound may be well illustrated by a case reported by Dr. Hoegh (*Medical News*, September 27, 1890). The patient, a girl, aged eleven, while walking barefooted on a barn floor covered with manure, trod upon a nail, which caused a punctured wound of the right foot about two inches behind the head of the second metatarsal bone. There was very little bleeding, but great pain, and swelling of the foot, with redness of the part, soon appeared. The pain continued till the third day, when the toes became white and insensible. At the end of three and a half days she was brought to hospital. The foot was now black and gangrenous up to the tarsal bones. There was no suppuration, but small gas-bubbles were seen. Œdema and purplish discoloration reached to the ankle, and there were streaks of lymphangitis up the leg. The nail-wound could not be seen. The temperature was 101° F., the pulse 120. The mind was dull, as if from partial collapse. There was great pain. On the following day the temperature was 103° F., the gangrene reached to the malleoli, and the œdema nearly to the knee. The leg was amputated above the knee. Rapid recovery ensued.

Bacteriologists tell us that in such cases the œdema and gangrene are caused by the introduction into the wound of the *bacillus of malignant œdema*, a microscopic organism belonging to the above-mentioned group of organisms which cannot grow in the presence of oxygen. This bacillus is extremely widely distributed, being present in almost all decomposing substances. The spores are found in every specimen of earth which has been impregnated with putrid fluids, and also in the dust of rooms, in the dust of rags, of hay, etc. It will not grow in an open surface-wound, but in order to active development the earth or dust which carries it must be deposited in the wound beneath the cutis in such a way that air cannot reach it. Then it grows rapidly and produces malignant œdema, followed by gangrene and rapid death of the patient. The bubbles of gas are said to be produced by a kindred bacillus which accompanies it.

Besides mankind, horses, sheep, and swine, but not neat cattle, are affected by it.

When such a wound has been received, and it is probable that it has been infected by the bacillus, artificial anæmia should be produced by Esmarch's bandage, and the wound should be laid freely open so that it can be seen and cleansed to its very bottom. It should then be thoroughly cauterized with galvano-cautery or hot iron, and dressed antiseptically. If malignant œdema occurs, amputation will save the patient's life.

"IF YOU GO TO COLORADO YOU CAN NEVER RETURN."

THE Seventh Annual Meeting of the American Climatological Association was held in Denver, Col., during the first week of September. The most interesting question under discussion, both to the physician and to the patient, was as to when a consumptive who has gone to Colorado can safely return to a lower altitude. It could not have failed to be suggestive to the very many consumptives who listened to this discussion to learn that physicians from Boston and other places along the sea-shore believed it safe for many patients to ultimately return to their homes; while the doctors from the high altitudes held that it was unsafe for a consumptive ever to return to a low altitude except for short periods of from four to eight weeks during the usual vacation months of July and August. The personal interest which some physicians feel for their patients at times obscures their clear comprehension of the relations which various phases of treatment hold toward each other. So in this instance the question of altitude has been confounded with the question of climate.

It appears to us that the treatment of tuberculosis, whether of the lungs or other tissues, is of two kinds, general and local. Under the general treatment comes the question of climate; under the local, that of altitude. During the past years very considerable advances have been made in the general, or, as it may more properly be called, hygienic treatment of tuberculosis. It is now generally accepted that tuberculosis under favorable conditions is a self-limited disease; and that if the patient can be kept alive long enough he will get well. To this end the hygienic treatment gives to the patient all that which will tend to improve his general well-being, such as proper and abundant food, the greatest possible number of hours in the open air and sunlight, the most perfect protection against colds and all provocatives of coughing, and such surroundings as shall be conducive to a cheerful frame of mind. It is more than possible that these things cannot always be best obtained in high-altitude resorts. The local treatment consists in the application of certain medicaments, medicated air, dry air, hot air, the pneumatic cabinet, the rarefied air of high altitudes, etc. The confusion has perhaps arisen because it has not been recognized that the rarefied air of high altitudes acts in the same way as excitants to coughing, namely, to increase the lung-activity. Functional activity of a tissue infected with tuberculosis favors suppuration and a rapid elimination of the infecting germs; functional rest favors a slow elimination by starvation. In a tissue such as the lung, if the tubercular focus be small and localized, and if the patient's strength be still sufficient, the suppuration and rapid elimination which the rarefied atmosphere of high altitudes gives favors a rapid and perfect cure. In support of this we find a unanimity of opinion among the members of the Association that cases of pulmonary tuberculosis coming to Colorado sufficiently early, as a rule, permanently recover. On the other hand, if the tubercular infiltration be diffuse, if the patient's strength be not good, or if the disease be well advanced, the functional activity induced by rarefied air tends to a rapid termination of the life of the patient. In this, too, the members were agreed, that many cases of phthisis in an advanced stage were made worse by going to Colorado. In a word, it would appear that there are certain cases that are more rapidly cured, and other cases that are more rapidly killed, in a high than in a low altitude.

News of the Week.

The Clinical Use of the Phonograph has been attempted in this country, but without very great results. Better success seems to have been obtained in London. The *British Medical Journal* says that Mr. Ernest Hart recently suggested to Colonel Gouraud that the phonograph might with great advantage be employed to record the characteristic changes in voice-sound which mark a variety of diseases, such as whooping-cough, laryngismus stridulus, and the characteristic forms of dysphonia indicative of some forms of hysteria, and partial paralysis of the vocal cords, dependent upon pressure upon the recurrent laryngeal nerve. This suggestion Colonel Gouraud readily acted upon, and Dr. Felix Semon kindly consented to select from his patients at St. Thomas's Hospital a few cases in which pathological varieties of phonation were present. This was carried out with great success, and on Tuesday night, at a social gathering at 38 Wimpole Street, at which a considerable number of eminent medical men happened to be present, the phonograph reproduced the characteristic vocalization of some of these diseases with the most realistic effect. The whoop of whooping-cough, with the intervening cries of the patient, were as vividly reproduced as if the child were in the room, and so also were the hoarse utterances of a case of stenosis of the larynx. The opinion was generally expressed that this new application of the phonograph to the purposes of diagnostic and clinical instruction constituted a solid gain for teaching, and probably for many other purposes.

Dr. Samuel Wilks's Eulogy of Dr. Handfield Jones. – SIR: It would give me great pleasure if you would afford me a small space to enable me to offer my tribute of respect to the memory of the late Handfield Jones. I am sure I can say, in the name of all pathologists, that his work has been of the best and most enduring character. Its value has been enhanced by the spirit in which it was undertaken. Handfield Jones, more than nearly all men whom I have known, worked in the *siccum lumen* of Bacon. He was a pure scientist, had no ulterior object before him in his researches but the discovery of truth, and thus his labors bore no fruit in practice or other pecuniary rewards. They were contributions to science, and

went simply to enrich the department of medicine to which he was devoted. I believe this was generally admitted, for I have heard, for example, some of our most distinguished men declare, when they were discussing the morbid changes in the lungs and blood vessels, how indebted they were to Handfield Jones's paper on "Fibroid Degeneration," published in the year 1854. I know of no one who worked in a more purely scientific spirit, and his ardor only ceased with his life, for it was but recently that he was making original researches on the degenerative changes in the vessels of the brain. As was his purely scientific spirit, so necessarily was his whole character, for he always seemed to me to be pursuing the most honest, simple, and blameless life. There are others who may gain larger and more popular fame, but it is fleeting and ephemeral, while the name of Handfield Jones will, while medicine has a scientific basis, forever endure. I am, etc., SAMUEL WILKS.

Points in the Diagnosis of Gastric Disorders.—Professor Ewald, says the *British Medical Journal*, in examining the condition of the œsophagus, attaches great importance to the sounds heard with the stethoscope placed on the pit of the stomach. The sounds which accompany and follow the act of swallowing are normally two, viz., the first, *Spritzgeräusch* (syringe gurgle); and the second, or *Luft-geräusch* (air gurgle). The first has no diagnostic value, and is often absent in cases of hysteria, etc. The second is of great significance, and when present denotes a normal contraction of the walls of the œsophagus; the absence of the sound signifies a stricture or obstruction of the middle or lower third of the œsophagus. The best tests for free hydrochloric acid are tropæolin and Günzburg's reagent phloroglucin vanillin. The routine examination of the contents of the stomach to determine the amount of acid present is carried out as follows: 10 cubic centimetres of stomach-contents are taken and two drops of phenolphthalein added thereto in a saucer. To this a standard one per cent. salt solution is added drop by drop from a graduated tube till the color changes to red. The percentage of acid present is determined by the amount of salt solution added, the normal acidity being between forty and sixty cubic centimetres of this graduated tube. The absorptive power of the stomach is determined by giving iodide of potassium internally; this should be found in the saliva in from fifteen to twenty minutes. To ascertain the motor power of the viscus, a capsule of salol (one gramme) is given, and the urine tested with perchloride of iron for salicylates. Another, less convenient, method is to give a definite quantity of oil by the mouth, and after a given interval remove the contents of the stomach and ascertain the quantity of oil still present.

"So much a Foot."—A bran-new graduate, fresh from the parting embraces of his *alma mater*, was called to attend an old lady suffering from tape-worm. Having relieved her of the parasite, he sent in an account for 10s. 6d., which the patient thought exorbitant and asked for particulars. These were given in the following terms:—"For delivering you of a tape-worm 10½ feet long, at a shilling a foot, 10s. 6d."—*Medical Press.*

Dr. Alfred Vogel, of Munich, well known for his work on Children's Diseases, died October 9th, in his sixty-first year.

Rates on Surgical Chairs.—The Inter-State Commerce Commission have ordered that the present rate on surgical chairs be reduced, in less than carloads, from double first-class to first-class, or a reduction of about one-half in the rate. This was what the rate was formerly for a long period of time, and until recently, when it was advanced to double first-class, under the analogies of classification.

A New Anti-fat Remedy.—Dr. M. M. Griffith affirms (*Indiana Medical Journal*) that pills made from the extract of poke-berries are a reliable anti-fat. "It has been my custom," says he, "to gather, in the fall after frost, a quantity of berries, express their juice, and evaporate it to the consistency of an extract, of which I make pills of three or four grains. The dose is two pills before each meal, sometimes increased to three or four."

The Didactic Lecture Must Go.—The medical college course has been lengthened to three years in almost every reputable college, and now, says the *Indiana Medical Journal*, it is time to take the next step in progress and abolish the didactic lecture. This is the view which the RECORD has advocated, and it is one which must in time be adopted.

Portrait of the Late Professor Joseph W. Howe.—The house staff and alumni of St. Francis Hospital, New York, have presented to that institution a fine life-like crayon portrait of Professor Joseph W. Howe, M.D., in commemoration of his long service as attending surgeon. It is fittingly hung in the operating-room, where he labored so skilfully and successfully.

The American Academy of Medicine will hold its annual meeting at Philadelphia, Wednesday and Thursday, December 3 and 4, 1890. Richard J. Dunglison, *Secretary*.

Queens Co. Medical Society, N. Y.—The semi-annual meeting of the Queens County Medical Society was held at Areson's Hotel, Mineola, on Wednesday, October 29th. The meeting was well attended and considerable interest was manifested in the discussions. Several new members were admitted.

Dr. R. L. Watkins is the name of the author of the excellent article in the last issue, entitled "Electrolytic and other New Uses of Storage Electricity." It was erroneously printed Watson.

A Hospital Bequest.—The City Hospital at Youngstown, O., has received $5,000 by the will of Miss Lucretia J. Althaus.

Dr. Strong, for many years superintendent of the Northern Ohio Asylum for the Insane, has resigned.

New Jersey State Medical Board.—At the recent first—meeting of the Board, held at Trenton, eleven candidates presented, and of these ten attained the necessary average of seventy per cent. and were passed.

Medical Achievements in China.—Dr. Kerr, a medical missionary at Canton, has, in the past thirty-six years, treated over 520,000 patients, and has prepared twenty-seven medical and surgical books. He has trained one hundred medical assistants, chiefly Chinese. China now possesses one hundred and four hospitals and dispensaries, at which, in 1889, more than 348,000 patients received treatment.

The King of Holland is seventy-four years of age; he has Bright's disease, uræmia, and dementia.

The Football Season is now at its height, and it has so far been free from many serious casualties. In England this is not the case, and the medical journals report mortalities almost every week. Medical opinion is setting decidedly against the game. In this country the rules against rough play are very stringent, and are apparently better enforced than they are in England.

Hospitals for Alaska.—Dr. Clarence Thwing, of Brooklyn, has accepted an invitation to establish one or more missionary hospitals in the Territory of Alaska, beginning at Sitka.

The Ambulance Surgeon has a rather unfortunate time of it. If he is behindhand he is abused; if he is in too much of a hurry he is blamed; if he thinks the patient will die on the way, and refuses to take him, he is censured; and if he takes the patient, and does get him to the hospital alive, the victim is announced to have been hustled to death. This is not a perfect world; but, take it all in all, our city ambulance system is probably better than that anywhere else.

The Marks of a Poor Physician.—Dr. Broadbent, in an address before the British Medical Association, says a mark of a weak medical man "is the indiscriminate use of stimulants in fevers, a ready resort to narcotics and sedatives, treatment directed to symptoms only, and a fondness for new drugs of high-sounding names."

The Curiosities of Blushing.—In a book on "Flushing and Morbid Blushing," Dr. Harry Campbell cites these cases: Man, aged twenty-seven. Was a soldier, but compelled by excessive blushing to give up his profession. Man, aged twenty-eight. Has recently had to give up the study of medicine through excessive blushing. Man, aged thirty-two, minister. Is so afflicted by blushing that he has latterly entirely given up duty. Another patient is a commercial traveller; and a telephone clerk is so badly affected that he turns scarlet even when speaking through the 'phone.

The Effects of Politics on Lunatic Asylums.—Dr. P. H. Kretzschmar, the presiding officer of the Board of Supervisors, at Brooklyn, has recently had occasion to write a very caustic veto touching a bill for repairs at the branch asylum for the insane at St. Johnland. The branch, also called the County Farm, is forty-two miles distant from the old asylum at Flatbush, and has proved an unexpectedly heavy burden on the taxpayers on account of "extras." It seems likely to cost the county only a trifle less than $2,000 per capita to simply house the pauper insane of that community, the cost of the land, chiefly farm lands and forests, being included. There are costly stone-built and fully equipped hospitals in our cities that have cost not more than $2,000 per capita, cost of the land inclusive; while some others, less ornate but equally well adapted to their purposes, have been constructed for $1,000 a patient. From the standpoint of the medical superintendent, the effect of the political pilfering of the pauper lunatic is deplorable.—*N. Y. Medical Journal.*

Succi, the Faster, began a forty-five days fast in this city, at 8 P.M., November 5th. We are informed that several members of the medical profession have undertaken to supervise his performance.

Dr. Roberts Bartholow and Jefferson Medical College.—On October 27th, the Trustees of the Jefferson Medical College declared vacant the Chair of Materia Medica, General Therapeutics, and Hygiene, which for eleven years past has been occupied by Professor Roberts Bartholow. It is stated that this action was taken because Dr. Bartholow declined to resign, despite his ill-health, which has made it impossible for him to perform the duties of the chair satisfactorily to the Trustees. We regret greatly to learn of Dr. Bartholow's illness. His work in the past, as an original investigator, writer, and teacher, has placed him deservedly in the front rank of American physicians.

A Dramatic Suicide.—A telegram from St. Petersburg announces the following startling episode: Dr. Kouchársky, a young professor of medicine, had just ended a lecture on acids when he poured some drops from a phial into a glass. "Attention, young men," he said; "in two minutes you will see a man die. Good-by to you all!" He drank the liquid, drew out his watch, and counted the seconds until he fell to the ground a corpse. The students were speechless and motionless; when they at last tried to apply antidotes it was too late, Professor Kouchársky was dead.

The Syms Operating Pavilion in connection with Roosevelt Hospital, will be finished in about a year. It will have a basement and three stories, with a conical dome sixty-four feet high. The operating arena will have rows of seats capable of accommodating one hundred and eighty-four students, and so steep that the rear seats are but twenty-eight feet away from the operating-table. The wall will be wainscoted with marble five feet above the highest seats. In the dome, forty feet above, will be three skylights ten by sixteen feet, and one twenty-two by twenty-eight feet. No wood will be used in any part of the amphitheatre.

Mr. Edison has given $1,000 to the benevolent institutions of Dresden, in recognition of the care and attention bestowed on a member of his family in one of the hospitals of that city last year.

Death from Methylene.—At the South Devon Hospital, Plymouth, England, bichloride of methylene is almost exclusively used as an anæsthetic. A death from its administration is reported by Mr. R. H. Hughes, occurring in a man aged fifty-one, with a fatty heart. This is the first death in about two thousand administrations.

Tomatoes and Cancer.—Why or wherefore it is impossible to say, but in some unaccountable fashion the impression has come largely to prevail among the public, that tomatoes are a cause of cancer, and that for this reason the delightful vegetable in question must be eschewed. The only connection that we know of between cancer and tomatoes is that within past years there has been a large augmentation in the death-rate from cancer, and an enormous increase in the consumption of tomatoes.—*Medical Press.*

Epidemic Blindness.—An epidemic of blindness, probably hysterical, is reported as prevalent among the working-girls of Wheeling, W. Va.

The Southern Surgical and Gynecological Association will meet in Atlanta, Ga., November 11th, 12th, and 13th.

A Novel Percussor.—Dr. Kabierski, of Breslau, has invented a novel percussor in the form of a tuning-fork with a cylindrical stem, which is held between the finger and thumb, and thin prongs with rounded free extremities for striking the surface of the body. He claims for this instrument that it distinguishes smaller areas from one another than the ordinary method of mediate percussion can do. He has mapped out by its means the varying movements of the apices of the lungs, and believes that he has shown that the boundaries of cardiac dulness as usually given require to be somewhat modified.—*Lancet.*

The Provost of the University of Pennsylvania announced, at the recent dinner of the medical alumni, that the compulsory course for the medical degree in that university had been lengthened to four years.

A Good Example.—The *Nordiskt Medicinskt Arkiv* is a monthly journal published at Stockholm by learned descendants of the Vikings. The name is not melodious, nor do its syllables drop from the lips like the melting music of the Italian speech, but the journal sets a good example to Italy, and arouses the kindliest feelings in our bosom as we take it up. For while the body of the journal is filled with original "Bidrags," "Bemärkninger," etc., there is an appendix in which summaries of these articles are given in French. This saves us from turning important Scandinavian literature over to our polyglot editor, who is at present much engrossed in practising the Chinese dialects, talking to himself in Russian, and answering in Czechish. The example of the *Nordiskt Medicinskt Arkiv* deserves imitation from other countries in Europe. The world is to have but three languages, English, French, German (and perhaps Bostonian); and the smaller nations of the globe would help their medical brethren if they recognized this.

Sanitation.—The Trades Union Congress is not a likely place for the ventilation of sanitary matters, but during that just held several matters of hygienic importance have been brought forward. With regard to insanitary factories, it was pointed out that the number of inspectors is insufficient. "Sweating" was a sanitary, as well as an economic, evil, for clothes were made under conditions calculated to spread disease, *i.e.*, in workshops where the workers had only from one hundred and twenty to one hundred and eighty cubic feet of space each, whereas convicts in prison had from four hundred to five hundred cubic feet. It was a mistake to imagine that only very cheap clothes were made in sweating dens; garments ordered for the Royal Family had been traced to the East End. A strong opinion was expressed at the Congress in favor of extending the provisions of the Factory and Workshop Act to domestic workshops; the laundresses' delegate wished all places where washing was done to be included. A resolution was also unanimously passed at the Congress in favor of the compulsory registration and examination of plumbers.

Tri-State Medical Association.—The Committee of Arrangements have postponed the next meeting of the Tri-State Medical Association until November 19th and 20th.

Post-graduate Schools.—Further post-graduate courses are about to be held in London and in Edinburgh. Similar instruction is also about to be inaugurated in several provincial medical schools.

A New Policlinic at Vienna.—An association of physicians and privat-docentens has been formed here, with a view of founding a new policlinic, where post-graduate courses will be given. It is believed that the opening of this new institution will take place in February next.

After July 1, 1893, the Colorado State Board of Health will accept the diplomas of no school which does not have an obligatory three years' course of instruction of five months each in three different years.

Atropia not a Specific in Enuresis.—In enuresis of children Dr. R. B. James found atropia often effective, so long as its administration was continued in full doses. But after leaving off the drug the patients were no better than before. His plan was as follows (*Archives of Pediatrics*, September, 1890): A solution of atropia sulphate was made, of which one teaspoonful represented one-hundredth of a grain of the drug. Of this solution, for the first night, each child had one teaspoonful at 6 and another at 9 P.M., and this to be increased by one teaspoonful every night till a controlling dose was reached for each case. None of them were benefited by less than four hundredths of a grain at night—that is, two hundredths of a grain at 6 and two hundredths of a grain at 9 P.M.—while others required as much as eight-hundredths of a grain (divided as above); one case was given as much as one-tenth of a grain at night without showing symptoms of poisoning. Nothing short of the quantity that produced full physiological effects was of any avail. After the controlling dose was ascertained for each case, it was repeated every night for about one month, when the drug was withheld altogether. It was found that many of the cases were relieved, while others were not benefited. Of the cases completely relieved, the enuresis returned in all, with one exception, in periods ranging from one to six weeks. The case that was cured was a healthy boy but slightly affected. These cases were kept under close observation for eight months, during which time many of them would go without the drug, or on reduced doses, from one to four weeks without wetting themselves. But sooner or later the relapse would occur, and at the end of the eight months they were but little better than when treatment was started.

Mortality in European Armies.—Recent statistics relative to the mortality among European troops in time of peace show that the Spanish army occupies the place of dishonor in this particular, with a death-rate of 13 per mille. Russia comes next with one of 9, then Italy with one of 7.74. Next in order come Austria with a mortality of, in round numbers, 7 in the thousand, France with 6, England with a little over 5, Belgium a little over 4, and Germany a little over 4. Consumption is rifest among English soldiers, and least prevalent among the French.

Reviews and Notices of Books.

MINERAL SPRINGS AND HEALTH-RESORTS OF CALIFORNIA: with a Complete Chemical Analysis of every Important Mineral Water in the World. By WINSLOW ANDERSON, M.D. Illustrated. Pp. 384. Cloth, $1.50. San Francisco: The Bancroft Company. 1890.

THIS handsome book, with its gold embossed binding, makes the patriotic American's bosom swell with pride, for it shows that the mineral springs of America, and especially of California, are as good as their famous sisters in Europe, and, as a rule, much more beautifully located. Balneotheraphy hasn't its proper place in America, for, though it is little used comparatively, the mineral waters have proven to be of great benefit in the alleviation and eradication of many of the most chronic and intractable diseases. In Dr. Anderson's work, the physician can obtain a proper knowledge of the subject, and learn where he can find invaluable mineral waters within comparatively easy access. The author is a well-known teacher of chemistry, and his book was awarded the last annual prize of the Medical Society of the State of California. He is also editor of the *Pacific Medical Journal*. These facts speak volumes in favor of the book and insure its reliability and pleasing qualities.

FIFTH ANNUAL REPORT OF THE STATE BOARD OF HEALTH OF THE STATE OF MAINE. For the fiscal year ending December 31, 1889. 8vo. Pp. 318. Augusta: Burleigh & Flynt. 1890.

THIS report contains very much of value and interest. Circulars have been issued for the use of teachers, school officers, and non-medical members of local health boards, giving the principal characteristics of the infectious diseases and their infection, and brief hints to prevent their spread. The one on consumption is especially complete. Analyses of one hundred and seventy-eight samples of water have been made, the essential points of which are given. Dr. Victor C. Vaughn contributes an interesting paper on "Healthy Homes for the Working Classes;" and Dr. A. G. Young on "Various Sanitary Topics," the remarks on tuberculosis and consumption, diphtheria, typhoid fever, and the various means for disinfecting being especially valuable.

A TREATISE ON MASSAGE. By DOUGLAS GRAHAM, M.D., Fellow of the Massachusetts Medical Society, etc. Second edition, revised and enlarged. 8vo. 342 pages. New York: J. H. Vail & Co. 1890.

THE first edition of this work was published six years ago; and it would, perhaps, have been better if the second edition had not been revised and enlarged. We do not need to be told that massage is not a new remedy; neither is it any longer an unknown one. Its indications are well known and its value recognized by the bulk of the profession. This present volume is interesting as far as the historical part goes, and it is valuable in so far as the details of the application of the remedy are concerned; but it cannot be of advantage to those interested in the subject to have put forward some claims which we find herein, to wit:

"The patient urinated by drops. Six centimetres behind the meatus was an impermeable stricture. Emollient applications having failed, Antal tried massage, and after three séances was able to pass a small metallic sound, and after seven days could pass an English sound, No. 13, and the callus had entirely disappeared."

"Dupuytren's finger contraction, consisting of hyperplasia and induration of the palmar fascia, the result of slight injury and reflex nerve irritation, has been successfully treated by means of massage."

"Habitual scoliosis arises from superincumbent weight, the original cause of which is weakness of the muscles, and therefore the treatment has to be directed to them. . . . After this the spinous processes are acted upon by stroking from behind upward, and pushing them directly toward the concave side so as to equalize the curves. . . . A well-schooled anatomical eye, therapeutical instinct, inclination to treat such cases, together with experience, will lead to accurate treatment and good results." The author attempts to bolster up his position by the name of Landerer. He evidentally knows no more of Landerer and his work than he does of the anatomy of scoliosis. In the same way he refers to Barwell and Billroth to support him in applying massage in cases of tubercular synovitis, apparently unconscious that the pathology and treatment have totally changed since Barwell first wrote, in 1861, on strumous synovitis, and Billroth on fungous inflammations. It is difficult to understand how anyone living within reach of modern medical literature can be so ignorant of the treatment of chronic joint disease.

Ignorance is not perhaps the worst feature of this book, for in the chapter on massage of the internal organs we find that "the operation consists in introducing an index-finger into the cul-de-sac behind the cervix in such a manner that the posterior surface is reached. This is then raised as far as possible, while the fingers of the other hand grasp and knead the uterus through the abdominal walls. Sometimes the uterus is pressed against the walls of the pelvis laterally, or against the posterior surface of the symphysis pubis." And we are then asked to read a report of two hundred and thirty-nine cases treated by this "operation."

With the exception of the parts referred to, the book is written in a very pleasing and interesting style; and is replete with appropriate quotations, like the following with which it closes:

> ". . . they at last a certain ease obtain
> From Katerfelto's skill, and Graham's glowing strain."

ELECTRICITY IN THE DISEASES OF WOMEN, WITH SPECIAL REFERENCE TO THE APPLICATION OF STRONG CURRENTS. By G. BETTON MASSY, M.D., Physician to the Gynecological Department of Harvard Hospital. Second edition. Revised and enlarged. Pp. xii. 240. Philadelphia and London: F. A. Davis, publisher, 1890.

THE appearance of a second edition of this little work within a year is sufficient proof of its popularity. It has been thoroughly revised and new chapters on the application of electricity to the treatment of subinvolution and diseases of the adnexa have been added. The first ten chapters are devoted to the theory and experimental results of electricity as applied to gynecology and the last ten to the special diseases in which it is useful. The law of Ohm is discussed in the appendix. The important subject of the electrical treatment of fibroid tumors receives the attention which it deserves. The chapters on menorrhagia and endometritis are especially valuable. In Chapter xv. the author leaves no doubt as to his conservative position with regard to the indiscriminate performance of laparotomy for disease of the adnexa, predicting a "reaction from this war-time in abdominal surgery." His views concerning the efficacy of galvanopuncture, though decided, are not tinged with that ultra-enthusiasm which has caused the statements of some ardent followers of Apostoli to be viewed with suspicion even by those who have little sympathy with the more extreme school of laparotomists.

The electrical treatment of pelvic pain, or "menorrhagia," as the author terms it, forms the subject of a suggestive chapter, which we regard as one of the most useful to the general practitioner, whose attention is directed to this symptom more frequently than to any other. The more widely the author's view, that dysmenorrhœa is "almost entirely a neuro-muscular phenomenon," is disseminated, the less frequent will be the tendency to resort to laparotomy for the empirical purpose of relieving vague pelvic pains. A chapter on

anteflexion and one on extra-uterine pregnancy (which seems to be too brief in view of the importance of the subject) are among the more important of those which conclude the volume. The style is clear, but condensed. Useless details are omitted, the reports of cases being pruned of all irrelevant material. The book is an exceedingly valuable one and represents an amount of study and experience which is only appreciated after a careful reading.

A Manual of Anatomy for Senior Students. By Edmund Owen, M.B., F.R.C.S., Surgeon to St. Mary's Hospital, London, and Co-lecturer on Surgery (Late Lecturer on Anatomy) in its Medical School. With numerous illustrations. London: Longmans, Green & Co. 1890.

An index to the nature of this admirable work is found in the quotation on the title-page from Francis Sibson: "In a practical point of view, anatomy is of no use unless it can be realized on the living body." And it is with the aim of aiding in this necessary realization that the author has written his book. That he has succeeded in making of the study of anatomy a real pleasure will not, we think, be denied by anyone who takes up the book. The subject is divided regionally and not according to systems, the only way, in our opinion, that a real knowledge of anatomy can ever be acquired, and the way in which it is learned practically by dissection. After treating briefly, though at all-sufficient length, of the anatomy of the parts, the author then applies the knowledge thus gained to practical points in medicine and surgery, both in the way of a diagnosis, and as a guide to operative measures. The work is said to be for the use of "senior students," but there are many "senior practitioners" who would derive no little profit from a careful perusal of its pages. They would find many things recalled that they had forgotten, and perhaps would learn some things that they had never known.

A Treatise on Orthopedic Surgery. By Edward H. Bradford, M.D., Surgeon to the Children's Hospital, Boston City Hospital, and Samaritan Hospital; Instructor in Clinical Surgery, Harvard Medical School. And Robert W. Lovett, M.D., Surgeon to the Samaritan Hospital; Assistant Out-patient Surgeon to the Children's Hospital; Out-patient Surgeon to the Carney Hospital; formerly Assistant Surgeon to the New York Orthopedic Dispensary and Hospital. Illustrated with seven hundred and eighty-nine wood-engravings. New York: William Wood & Co. 1890.

The need of a treatise on orthopedic surgery has long been felt in this country, the only work of the kind being that of Sayre. This department of surgery is still in its infancy, or at best just learning to stand alone, and consequently we cannot expect to find any settled and authoritative methods of treatment. It is therefore well to have more than one text-book on the subject, so that the student and young practitioner may at least have a choice of methods, and need not follow unreasoningly the teachings of any one authority. The work before us is rather formidable in appearance, containing nearly eight hundred octavo pages, but the subject is a vast one, and has long since outgrown the monograph stage. In this book the consideration of diseases of the joints, including Pott's disease of the spine, occupies nearly one-half of the volume, so that the space devoted to the treatment of deformities, or orthopedic surgery, properly speaking, is not excessive. Each subject is treated in a most thorough manner, and is fully illustrated by well-executed wood-cuts. The authors seem to have endeavored to avoid therapeutic dogmatism, and have presented all the chief methods of treatment of the various deformities and joint diseases without passing too positive judgment on them. The young surgeon who is looking for instruction in this branch of his profession cannot go wrong in getting this work. He will find there almost everything that is of value, and in later life he will have but little to unlearn, however much additional knowledge he may acquire from his own experience.

Sanitary and Economic Cooking. By Mary Hinman Abel.

The Lomb Prize Essay of the American Public Health Association. A general discussion of the principles of cooking, especially adapted to persons of small and moderate means; contains a valuable collection of recipes for the preparation of the various kinds of food. An excellent book for nurses and mothers.

An Experimental Study of Lesions Arising from Severe Concussions. By B. A. Watson, M.D. Philadelphia: P. Blakiston, Son & Co. 1890.

This pamphlet of seventy-six pages records the results of a series of 141 experiments, made to determine, if possible, the lesions in those cases commonly called concussion, which have previously been described by Erichsen and Page. We have not space to describe in detail the apparatus used. The animals experimented upon were dogs, and they were dropped suddenly from a height. In each experiment the temperature was recorded for a certain time immediately after and a post-mortem made. The records are systematic and accurate, and well deserve the perusal of surgeons, particularly of those who have to do with the results of railroad injuries.

Field Hospital Service with the Army of the Potomac. By William Warren Potter, M.D., Buffalo. *Buffalo Medical and Surgical Journal* reprint.

The writer entertainingly describes his three years' experience as a medical officer in the above army. Much interesting war history is interwoven in the narrative; several photo-gravure pictures illustrate the text.

Evolution and Disease. By J. Bland Sutton. Pp. 284. New York: Scribner & Welford. 1890.

This is an interesting study in comparative anatomy, normal and pathological. The chapter headings are: The Enlargement of Parts from Increased use, Overgrowth and Irritation, Disuse and its Effects, Vestigial Parts, Dichotomy and Atavism, or Reversion. The pages are profusely illustrated with wood-cuts, and so plainly written as to be easily understood. Mr. Sutton's contribution to the "Contemporary Science Series" deserves unqualified commendation.

Ætiology of Tuberculosis. By Dr. Robert Koch, translated by T. Saure. Reprint from Transactions of the Massachusetts Veterinary Medical Association. New York: W. R. Jenkins. 1890.

This is Koch's elaborate monograph, which is too well known to need comment here.

Massage: a Primer for Nurses. By Sarah E. Post, M.D. 16mo. Pp. 50. Six Illustrations. New York: The Nightingale Publishing Co., 13 West 42d Street. 1890.

This little volume is intended solely for the instruction of nurses; but within its fifty pages it contains more valuable information on the use of massage than any other book on the subject with which we are familiar. Not only is it replete with valuable instruction and sound common sense, but, what is much more rare, it does not contain one unnecessary sentence.

On that much-vexed question of massage of the pelvic organs it is refreshing to read: "Applications of pelvic massage may vary in length from three minutes to three-quarters of an hour." It is not probable, however, that nurses will, for the present at least, be required to undertake this treatment

TRANSACTIONS OF THE NEW YORK STATE MEDICAL ASSOCIATION FOR THE YEAR 1890. Vol. VI. Pp. 445. Ten Illustrations. Edited by Edward K. Dunham, M.D. New York: J. H. Vail & Co.

THIS volume of transactions is an especially interesting one. There are many papers, but they are short and to the point. Of the President's Address—Tubal Pregnancy, by Dr. William T. Lusk—it is not necessary to speak; we all know the worth of all that he writes. Dr. George E. Fell describes a new position, the Latero-dorsal, in Gynecic Irrigation; Dr. T. D. Crothers, Alcoholic Paralysis; and Dr. John Shrady, the Shadow-line of Insanity. The subject of Hernia receives a very extended consideration, there being papers by Drs. Joseph D. Bryant, S. E. Milliken, T. H. Square, E. M. Moore, Roswell Park, W. T. Bull, D. M. Totman, and L. J. Brooks. Of the remaining papers, perhaps none are more interesting than a report of one hundred successful cases of Extraction of Cataract without Iridectomy, by Dr. C. S. Bull, and New Hypnotics, by Dr. William H. Flint.

TRANSACTIONS OF THE MICHIGAN STATE MEDICAL SOCIETY FOR THE YEAR 1890. Vol. XIV. 8vo. Pp. 480. Detroit: O. S. Gulley, Bornman & Co., printers.

BESIDES the President's Annual Address, by Dr. George E. Frothingham; the address on Surgery, by Dr. F. J. Groner; the address on Practice, by Dr. W. F. Breakey; and the address on Obstetrics and Gynecology, by Dr. J. N. Martin, this volume contains thirty-one interesting and valuable papers, a full review of which we have not the space to give.

TRANSACTIONS OF THE AMERICAN ORTHOPEDIC ASSOCIATION. Third Session. Vol. II. 8vo. Pp. 296. Twenty-eight Illustrations. Published by the Association.

THE volume is a very creditable production for a society of only forty-four active members. Thirteen papers appear bearing upon the subject of Hip Disease from various points of view. They are by: Drs. R. W. Lovett, Joel E. Goldthwait, N. M. Shaffer, Henry Ling Taylor, A. J. Steele, DeForest Willard, R. H. Sayre, John Ridlon, A. B. Judson, W. R. Whitehead, Bernard Bartow, E. G. Brackett, and John H. Huddleston. Dr. V. P. Gibney appears with a paper on Typhoid Spine; Dr. Louis A. Weigel, on the Relation of Thoracic and Abdominal Walls to the Spinal Column, Considered with Reference to the Treatment of Antero-Posterior Curvatures; Dr. Dillon Brown, on Psoas Contraction as a Symptom; Dr. C. C. Foster, on a Case of Caries of the Ankle; Dr. C. L. Scudder, on a Report of Eighteen Cases of Chronic Disease of the Ankle; Dr. John Ridlon, on a Report of a Case of Congenital Dislocation at the Hip; Dr. George W. Ryan, on When may Treatment be Dispensed with in Spondylitis; Dr. R. W. Lovett, on a Case of Functional Torticollis; Dr. Homer Gage, on Congenital Absence of Five Ribs; Drs. W. N. Bullard and H. L. Burrill, on Surgical Operations for the Relief of Pressure Paralysis in Caries of the Spine; Dr. Henry Ling Taylor, on the Treatment of Pes Equino-varus by Continuous Leverage; Dr. W. R. Townsend, on Acute Arthritis of Infants; Dr. V. P. Gibney, on a Contribution to the Study of Flat-foot; and Dr. T. Halsted Myers, on Traumatism of the Hip Simulating Thyroid Dislocation.

TRANSACTIONS OF THE AMERICAN SURGICAL ASSOCIATION. Vol. VIII. 8vo. Pp. 290. Fourteen Illustrations. Edited by J. EWING MEARS, M.D. Philadelphia: P. Blakiston, Son & Co. 1890.

WE can only direct attention to the interesting and valuable papers in this volume. Many of them have been elsewhere published and read; those that have not will well repay a careful perusal. The one perhaps of most general interest is A Sketch of Pioneer Surgery in Kentucky, by Dr. David W. Yandell, in which are detailed the struggles and successes of Brashear, McDowell, McCreary, and Dudley.

Dr. P. S. Connor follows with a tabulated statement on the Surgical Treatment of Tumors of the Bladder. Dr. Stephen Smith takes up the consideration of the Treatmen of Fractures of the Shaft of the Femur. And Dr. C. B. Nancrede and Dr. Heneage Gibbes report a Rare Form of Epithelioma of the Hand. Dr. Thomas G. Morton writes on the Pathology and Treatment of Club-foot, and reports on fifteen cases of excision of the astragalus. The operation of excision of the astragalus is comparatively recent. The first report was made by Mr. Lund in the *British Medical Journal*, October 19, 1872. Since that time a number of operators have reported successful cases, but we do not know of so interesting a group of cases as those reported by Dr. Morton, to whom is due great credit for bringing prominently forward an operation which far surpasses any other for the relief of a certain class of cases of inveterate club-foot.

Dr. W. T. Bull reports on the Radical Cure of Hernia, with the results of one hundred and thirty-four operations. Various methods were employed, but the writer comes to the conclusion that all methods of radical cure will be found unsatisfactory. Dr. C. H. Mastin reports a case of rare Lumbar Hernia. Dr. F. S. Dennis, in a very able paper, discusses the Propriety of the Removal of the Appendix Vermiformis during the Intervals of Recurrent Attacks of Appendicitis. And Dr. J. Ransohoff reports a case of Rupture of the Middle Meningeal Artery without Fracture.

Dr. W. W. Keen tabulates one hundred and thirty-four operations for Nephrorrhaphy, and gives a very careful consideration of the same. Dr. J. A. Comingor discusses the question of Hypertrophy of the Prostate. Dr. David W. Cheever reports briefly a case of Lupus of the Tongue, and a case of Retro-pharyngeal Sarcoma, removed by an external incision through the neck. Dr. Hunter Maguire makes a report on twenty-one cases of Supra-pubic Cystotomy which he has done during the past two and a half years. The interesting point of his operation is that he distends the rectum with an inflated rubber bag, and thus makes the bladder prominent when it contains only a small quantity of fluid. Dr. J. William White, in an exhaustive paper on Antisepsis in the Treatment of Recent Anterior Urethritis, advises the administration of capsules containing salol, three and a half grains; oleoresin of cubebs, five grains; Para balsam of copaiba, ten grains; and pepsin, one grain. Dr. E. H. Bradford sums up a paper on Arthrectomy of the Knee-joint with the following: In one case, motion to ten degrees was obtained after a thorough operation. In one case a sinus resulted and remained for several months. Whether motion be gained in the ultimate result or not, will depend upon the extent of the disease and the thoroughness of the operation.

Dr. Robert Abbe reports two cases of Paranephric Cysts, and discusses the subject in an able paper. Dr. O. H. Allis writes on Fractures and Disjunctures of the Pelvis, and briefly reports on seven cases. And Dr. A. G. Gerster closes the volume with a learned paper on the Removal of a Tubercular Tumor of the Larynx by Laryngo-pharyngotomy.

PHILOSOPHY IN HOMŒOPATHY. By CHARLES S. MACK, M.D. Chicago: Gross & Delbridge. 1890.

THE writer is Professor of Therapeutics in the Homœopathic College of the Ann Arbor University. This book consists of addresses delivered and papers read on various occasions. The writer is evidently a believer in Swedenborg, as he is a reader of and contributor to the *New Jerusalem Magazine*. Two of these latter productions are appended to the "Philosophy."

The writer is a man of temperate views, and does not make any vicious attacks on the "old school." His style is rather obscure in places, and we do not think that he always makes the strongest possible presentation of his cause.

Society Reports.

MISSISSIPPI VALLEY MEDICAL ASSOCIATION.

Sixteenth Annual Meeting, held in Louisville, Ky., October 8, 9, and 10, 1890.

FIRST DAY, WEDNESDAY, OCTOBER 8TH.

PRESIDENT, DR. J. M. MATHEWS, OF LOUISVILLE.

Infectious Dyspepsia, and its Rational Treatment by the Antiseptic Method.—DR. FRANK WOODBURY, of Philadelphia, Pa., said that it was proper to state that our present consideration of the subject is limited to dyspepsia solely as related to the stomach; no reference was attempted, or intended to be made, to intestinal indigestion, or to the so-called intestinal dyspepsia.

With reference to the pathology of dyspepsia, he considered it at least as much entitled to recognition as a distinct disease, in the present unsettled condition of medical nomenclature, as consumption or chorea. Like them, it is characterized clinically by manifestations of nervous disorder. Like pulmonary phthisis, its most marked symptoms are produced by the absorption of the products of parasitic micro-organisms.

Dr. Woodbury summarized as follows: Laborious, painful, and imperfect digestion occurring habitually, when not symptomatic of other disease, constitutes dyspepsia; and when accompanied by fermentation of the contents of the stomach and general toxic symptoms, the result of microbian development, it may properly be called infectious dyspepsia.

The disorder is sufficiently prevalent, and gives rise to enough discomfort and actual suffering in its victims not only to deserve our serious consideration, but also to enlist our best therapeutic skill in their behalf. The excessive growth of micro-organisms during digestion is favored by slow movements of the stomach, and by defective quantity or quality of the gastric juice. Acid dyspepsia, or sour stomach, may be due to excessive secretion of hydrochloric acid (rarely), but is generally caused by lactic, acetic, or butyric fermentation, due to the presence of appropriate forms of bacteria in the stomach. The object of treatment of infectious dyspepsia is to prevent the excessive development of micro-organisms during the digestion of food. This is sought to be accomplished, (1) by the use of articles of diet which are not in a fermenting condition, nor readily fermentible; (2) by adopting such hygienic and tonic measures as will invigorate the bodily powers, and especially bring the gastric juice up to its normal standard of quality and quantity, and increase the muscular power of the stomach; and (3) by local antiseptic treatment, including the administration of drugs which retard fermentation, and especially by lavage or irrigation of the stomach with weak disinfectant solutions, or simply recently boiled water.

Help and Hindrance to Medical Progress.—DR. JOHN H. HOLLISTER, of Chicago, said the possibility of progress is conditioned upon the imperfection of present attainment; results are dependent upon our abilities, upon our methods, and upon the obstacles to be overcome. The profession must command a much higher average of native talent; that talent must receive a much higher grade of culture; and the present methods of research on the part of the profession must be greatly modified and improved.

Coffee.—DR. I. N. LOVE, of St. Louis, said that his experience for five or six years past is strongly in favor of taking a cup of strong, black coffee, without cream or sugar, sandwiched in between two glasses of hot water, before rising every morning—at least, one hour before breakfast. Another cup at four in the afternoon is sufficient to sustain the energies for many hours. In this way the full effect is secured.

Mechanical Obstruction in Diseases of the Uterus.—DR. GEORGE HULBERT, of St. Louis, submitted the following conclusions: 1. That in the natural or normal order of things, we find the uterus in form and structure, endowed with a power and capacity for the performance of the function, menstruation, far in excess of any legitimate demand, to the extent that, with a one-fourth inch diameter of canal at the sphincters, the excess equals 7724.8 times the demand, and with a one-thirty-second inch diameter, the excess equals 120.7 times the requirement. 2. That in the pathological conditions, considered as essential for mechanical obstruction, we find that the conservation of force is capable and does so regulate conditions that the capacity is not abolished, but persists in an eminent degree, so that in the presence of the normal physiological energy, the function is accomplished, save in only one emergency, that of total annihilation of the normal state, namely, atresia. 3. That the phenomena considered as attendant and dependent upon mechanical obstruction, are not due to the forcible expulsion of retained fluids through the uterine canal, but are resident and produced within the tissues, and are dependent upon disturbed rhythm of physiological forces, evolved through abnormal enervation, muscular action, and circulation. 4. That the demand upon the uterus for the passage of blood-clots, membranes, mucous plugs, uterine sounds, sponge-tents, uterine dilators, etc., in order that the diagnosis of mechanical obstruction may be made, is not only vicious in the extreme, but irrational, illogical, and unscientific. 5. That the correct and rational interpretation of the testimony offered by symptomatology, pathology, and therapeutics, removes mechanical obstruction from the domain of gynecology, as a demonstrable fact, save in "atresia uteri."

The Surgical Treatment of Uterine Fibroids.—DR. R. STANSBURY SUTTON, of Pittsburg, Pa., made (by invitation) some remarks, and exhibited specimens.

Professor Flint's Doctrine of the Self-limitation of Phthisis.—DR. WILLIAM PORTER, of St. Louis, said that some time before his death Professor Flint promulgated the doctrine of self-limitation of phthisis, and presented it with all of his well known power and great ability to the profession. This very interesting proposition was at the time the subject of free debate in various medical societies. After having carefully examined the facts cited in support of the proposition, Dr. Porter said he had no hesitation in asserting that he finds no sufficient evidence to warrant us in accepting the statement that phthisis is self-limiting, or that the element of self-limitation has a decided influence upon the result in any given case. He did not mean that all cases of phthisis necessarily die from this disease, but he does mean that where phthisis is firmly established, there is nothing in the nature of the disease itself that indicates in any stage a fixed boundary—a line of demarkation, as it were—but rather that all of its tendencies are progressive and downward.

Cough: its Relation to Intra-nasal Disease.—DR. A. B. THRASHER, of Cincinnati, said cough is a reflex phenomenon due to the irritation of a nerve-fibre in the air-tubes, larynx, pharynx, nose, ear, stomach, etc. A normal cough is for the purpose of freeing the air-tract from some foreign body. Irritation of the upper part of the trachea, and the ventricles of Morgagni, most frequently produces cough. An irritation in many other locations may be referred by the sensory centres to this region, and thus give rise to cough. Inflammation of the cavernous bodies of the nose or of the adjacent septum has been known to give rise to a distressing cough, and has been mistaken for evidence of tubercular disease. This is more apt to occur in a person of neurotic temperament. The cough due to nasal disease may sometimes be recognized by its metallic ring and the absence of expectoration. It can, as a rule, be provoked at will, by touching the irritable spot in the nose with a probe. Dr. Thrasher recited three cases illustrative of nasal cough from his private practice.

The Medical Student.—DR. JOHN A. WYETH, of New York, said the first or preliminary stage of a medical

student's life is his preparatory or academic life; the second, his medical college life; the third, his post-graduate or practical life, and it extends from the day he leaves his alma mater until usefulness ceases. In the acquirement of a practical training three ways were open, and in order or preference they are: 1. Service as interne, preferably for a term of two years in a general hospital. 2. Service in some post-graduate institution where all departments of practical medicine are taught by teachers especially trained in their respective branches. 3. Service as assistant to one or more well-qualified practitioners in general medicine.

SECOND DAY, THURSDAY, OCTOBER 9TH.

Cases of Penetrating Stab-wounds of the Abdomen, Laparotomy, Results.—DR. H. C. DALTON, of St. Louis, reported six cases of laparotomy in which there was visceral injury. There was one death, and five recoveries. He laid particular stress upon the necessity of following the wounds to the bottom, and making ocular inspection of the same, and severely condemned the method of trusting to the introduction of the finger in the tactus eruditus. He deprecated depending implicitly upon Senn's hydrogen gas test, on account of its fallibility.

Gun-shot Wound of the Intestine.—DR. M. T. SCOTT, of Lexington, Ky., reported a case in which there were four perforations by a large bullet, various complications, and complete recovery following laparotomy (see p. 516).

Torsion of Arteries as a Means for the Arrest of Hemorrhage.—DR. J. B. MURDOCH, of Pittsburg, said there are two methods by which the torsion may be applied: 1, Limited torsion, and 2, free torsion. In the first method two pairs of forceps are required. The first pair grasps the vessel at its cut extremity, and pulls it from the sheath. It is then seized by the second pair at a point from one-half an inch to an inch above the cut extremity of the artery; this second pair being held at right angles to the long axis of the vessel. The first pair is then given three or four sharp turns. By the second method (free torsion) only one pair of forceps is required. It is the one recommended by Mr. Byrant, as not being so likely to injure the external coat of the artery. Dr. Murdoch said in conclusion that the advantages of torsion as compared with ligation are: 1. The greater facility with which it can be applied. 2. Torsion is a safer method, being less liable to be followed by secondary hemorrhage. 3. Healing is facilitated because the wound is free from any irritating or foreign body.

Skulls.—DR. G. FRANK LYDSTON, of Chicago, exhibited the skulls of a number of the most notorious criminals of the world, and made some very instructive remarks with reference to their peculiarities, shape, size, etc.

Wiring the Separated Symphysis Pubis, Supplemented by a Novel Pelvic Clamp.—DR. W. P. KING, of Kansas City, reported a case of separation of the symphysis pubis, with fracture of the interposed fibro-cartilages, fracture of the descending ramus of the pubis, with deep lacerations of the surrounding soft parts, and, more particularly did he refer to the methods resorted to in order to support the pelvis and reinforce the stitches after the pubis had been wired together.

Inguinal Colotomy.—DR. ARCH DIXON, of Henderson, Ky., said: As a measure intended to ward off imminent death, colotomy is called for in all cases of obstruction in the colon, from whatever cause arising. For imperforate anus the operation holds a special position. It is intended to prevent impending death, but it may or may not be regarded as a cure for the disease. In many cases it is the first step in the process of cure. In every infant born with imperforate anus, an operation of a local nature is first attempted; if this fails, colotomy by some method is performed to ward off death. Later on, an attempt may be made to get the bowel to discharge through the anus. In a few words, it may be said that the indications to operate in any given case, depend, in the first place, on the chance which the patient has of getting well without operation; and, in the second place, upon the degree of probability of success following the operation. To cases of acute obstruction of the sigmoid flexure, or elsewhere, there is practically but one termination—death. No case of volvulus, whether of large or small intestine, has as yet been known to recover under treatment purely medicinal. Here then the indication is clear enough, as clear as the indication to tie a bleeding carotid—operation.

Hypnotism in its Relation to Surgery.—DR. EMORY LAMPHEAR, of Kansas City, reported a case of double talipes in which the subject had a chronic Bright's disease, which contra-indicated the use of ether, and, at the same time, had an organic heart trouble, which prevented the safe use of chloroform. The patient wanted to be operated upon, and the doctor hesitated to give the ordinary anæsthetic, and so hypnotized him. This was the first séance, and contrary to the generally accepted idea that at the first séance a sufficient degree of anæsthesia cannot be produced to effect an operation, even at the first séance a sufficient degree of anæsthesia was obtained by suggestion to enable him to perform the operation.

Another case, reported by the permission of DR. SHAW, of St. Louis, was a patient suffering from Jacksonian epilepsy, due to brain tumor. He was hypnotized, the scalp cut, an inch and a half trephine used, the dura mater opened, and a brain tumor weighing one ounce and a half, removed. The bone was replaced, and the operation completed, occupying an hour, without either chloroform or ether being used.

Certainty in the Diagnosis of Tuberculosis.—DR. THEODORE POTTER, of Indianapolis, said the lack of specific curative treatment and of any great tendency to self-limitation after once well under headway, the destruction of tissue, the existence of subtle predisposing as well as exciting elements, the establishment of the vicious circle, including the organs and channels of nutrition, the strange and often persistent delusion of hope, and finally the possibility of arrest or real cure; these factors call in a peculiar way for early treatment. But this must depend upon early diagnosis.

In spite of the constant progress from Laënnec and Flint, there is no one sign and no combination of signs which is absolute. There is always some uncertainty, and in the early or unusual cases we are, and often long remain, uncertain. But now, with the new light of the present added to the knowledge of the past, we are able to make the diagnosis in the great majority of cases, not only early but with absolute certainty.

The Hypodermic Use of Arsenic.—DR. HAROLD N. MOYER, of Chicago, said the hypodermic use of Fowler's solution has been recommended by various writers, who claimed that the dose which could be administered in this way was much greater than could safely be administered by the mouth, Hammond having given as high as fifty drops of Fowler's solution as an initial dose. Again, he has often carried the amount given by the mouth to the utmost bounds of prudence, till the eyes were puffed, and vomiting was almost incessant, and then has continued the arsenic in larger doses, by the hypodermic injection, with the result of the cessation of all gastric symptoms and the cure of the disorder.

In a case of chorea, aged fourteen, female, the patient was placed immediately upon the hypodermic, beginning with three minims of the five per cent. solution, and increasing every second day, until, three weeks after beginning treatment, she was receiving thirteen minims of the solution at each injection, with an arsenic equivalent to about thirty-six minims of Fowler's solution. At the ninth injection she was discharged, cured.

THIRD DAY, FRIDAY, OCTOBER 10TH.

Perineal Cystotomy versus Supra-pubic Cystotomy.—DR. H. O. WALKER, of Detroit, said, in the choice of

method of operation we should be governed, 1, as to its safety; 2, as to its simplicity of performance; 3, as to its rapidity of result; 4, as to its general applicability in the majority of cases. He reported several cases in which he resorted to the perineal method. The perineal method of reaching the bladder is the oldest known to us, although numerous modifications have been made since the hap-hazard "cut on the gripe" for stone was first done. For the removal of stone, litholopaxy undoubtedly stands pre-eminent, and can be done upon subjects from three years of age upward; yet there are numerous restrictions to this method, such as stricture of the urethra, large-sized stone, an enormous prostate, etc. There can be no question, when cutting has to be done, that the medio-bilateral method presents the best advantages.

Two Cases of Tubal Pregnancy.—DR. EDWIN WALKER, of Evansville, Ind. The first case, Mrs. E. S——, aged twenty-seven, married four years; sterile. She had a history of uterine and tubal trouble before marriage. Since marriage she had been an invalid, suffering pain in the right groin. Menses always irregular, often missed a month or two. Was unwell June 20, 1890, but in July missed her menses. A few days later she began to suffer severe pain in the right groin. August 1st, sanguineous flow began and continued to time of operation. An examination under ether revealed a soft tumor the size of the fist to the right and behind the uterus. August 17th, abdomen was opened and the right tube, which was very large, found ruptured and large amount of clotted blood in the pelvis; fœtus not found; abdomen irrigated with hot water; glass drainage-tube used. Some vomiting and pain, but recovery ensued without a bad symptom. Drain removed on the third day, and sutures on the twelfth day. Highest temperature was 101.1° F. The author thinks that the present status of the question is, that with such a class of symptoms as presented in this and other cases, laparotomy is the safest procedure to adopt.

Resume of Experience to Date, all over the World, in the Various Operations of Cystitis from Prostatic Hypertrophy.—DR. WILLIAM T. BELFIELD, of Chicago, had collected 133 cases of operations upon the hypertrophied prostate, including 8 of his own, as follows: 41 by perineal incision, mortality, nine per cent.; 88 by suprapubic cystotomy, mortality, sixteen per cent.; 4 by combined perineal and supra-pubic incision, none fatal.

In 56 of these cases the essential facts before and after operation are furnished; they had been the subjects of cystitis and dependent upon the catheter for periods varying from one to ten years. In all the cystitis was cured; in 38 (two-thirds), voluntary urination was restored and continued during the time of observation, six months to two and a half years; in 18 this function was not recovered.

Fifteen of these 56 cases were complicated with stone; excluding these, since it might be objected that the cure resulted rather from the calculus extraction than from the prostatic operation, there remain 41 cases of uncomplicated prostate operation; of these, 32 (four-fifths) recovered the power of urination; in 9 this ability was not recovered.

Treatment of Organic Stricture of the Male Urethra.—DR. SEATON NORMAN, of Evansville, Ind., said in the practice of urethral surgery the operator cannot be too emphatically impressed with the fact of the requisite tenderness and sensitiveness of the urethra, and the employment of the slightest amount of force in the introduction of an instrument should be regarded as a relic of barbaric surgery. When commencing the treatment by gradual dilatation, in sensitive patients, he always produces local anæsthesia by the injection of twenty to thirty minims of a four per cent. solution of hydrochlorate of cocaine. Relative to internal urethrotomy, he believes that when it is properly and thoroughly executed, and special care is exercised to maintain the patency of the canal until the wound is entirely healed, that reconstraction is of rare occurrence.

The Application of Antiseptic Methods in Midwifery Practice.—DR. L. S. MCMURTRY, of Louisville, Ky., in some impromptu remarks, said many medical practitioners can remember the time when they heard that the wards of certain hospitals were closed and undergoing renovation because puerperal fever had become epidemic in such institutions. The hospital to-day is the safest place in which a woman can be confined. A few years ago, led by Fordyce Barker, we were taught that puerperal fever was an entity, a distinct fever, dependent upon a separate materies morbi, just the same as malarial fever is an entity. To-day we know that puerperal fever so-called is a septic peritonitis, just the same as when a woman becomes infected after abdominal section, or after wounds of the peritoneum from any cause, or from infection of the endometrium and through the Fallopian tubes to the peritoneum. A woman after labor is a wounded woman. She has undergone certain physiological processes; she has received certain injuries in the process of labor which opened the lymphatic channels, by which she may have become infected from without. There is no such thing as a woman having a peritonitis unless she is infected from without. To prevent this infection the vagina must be sterilized, the bed surgically clean, the examining finger clean, the nurse clean, and the atmosphere as approximately aseptic as it is possible to make it.

Officers for 1891.—*President*, Dr. C. H. Hughes, of St. Louis, Mo.; *First Vice-President*, Dr. John H. Hollister, of Chicago, Ill.; *Second Vice-President*, Dr. S. S. Thorn, of Toledo, O.; *Secretary*, Dr. E. S. McKee, of Cincinnati, O.

Next place of meeting, St. Louis, Mo., third Wednesday in October, 1891.

Correspondence.

DERMATOLOGICAL INSTRUCTION IN AMERICA.

TO THE EDITOR OF THE MEDICAL RECORD.
